[Top of Page]

Symbols

***a*:** exponent in Freundlich equation

***a*:** specific internal surface of adsorbent, m^2/kg

***a*:** thermal diffusivity, m^2/s

a_{sch}: volume-related surface area of packing, m^2/m^3

***A*:** factor in Freundlich equation, mol/g

***A*:** cross-sectional area, m^2

***b*:** factor in Langmuir and BET equations

c_B: bulk concentration, kg/m^3, mol/m^3

c_S: surface concentration, kg/m^3, mol/m^3

c_i: concentration of component *i*, kg/m^3, mol/m^3

c_i^*: concentration of component *i* at equilibrium, kg/m^3, mol/m^3

$c_{M,i}$: concentration of component *i* in the macropore, kg/m^3, mol/m^3

c_p, c_s: specific heat capacity of fluid or adsorbent, $J\ kg^{-1}\ K^{-1}$

c_0, *i*: concentration of component *i* at entrance to fixed bed, kg/m^3, mol/m^3

***C*:** structural parameter in Dubinin–Radushkevich equation

***d*:** gas-kinetic molecular diameter, m

***d*:** particle diameter (= $2\ R_a$), m

d_A: gas-kinetic molecular diameter of component A, m

d_B: gas-kinetic molecular diameter of fluid B, m

d_M: macropore diameter, m

***D*:** bed diameter, m

D_{ax}: axial dispersion coefficient, m^2/s

D_{AB}: diffusion coefficient of component A in fluid B, m^2/s

D_{eff}: "effective" pseudomacropore diffusion coefficient, m^2/s

D_{Kn}: Knudsen diffusion coefficient, m^2/s

D_m: diffusion coefficient in micropores, m^2/s

D_M: diffusion coefficient in macropores, m^2/s

D_0^0: basic micropore diffusion coefficient, m^2/s

D_S: surface diffusion coefficient, m^2/s

***e*:** exponent in Dubinin - Radushkevich equation

***E*:** energy, J

E_a: activation energy, J/mol

$F = \dot{v}\sqrt{\rho}$: F factor, $(\mathrm{m/s})\sqrt{\mathrm{kg/m^3}}$

ΔG: molar Gibbs free energy, J/mol

Δh: specific heat of adsorption, J/kg

Δh_B: specific heat of binding, J/kg

Δh_{LG}: specific heat of evaporation, J/kg

ΔH: molar heat of adsorption, J/mol

ΔH_B: molar heat of binding, J/mol

ΔH_{LG}: molar heat of evaporation, J/mol

h_i: Henry coefficient, mol m^2 g^{-1} N^{-1}

k: Boltzmann constant ($k = 1.38 \times 10^{-23}$ J/K)

k: factor in binary Dubinin equation

k: number of adsorbable components

k_{ad}: rate constant for adsorption, g mol^{-1} s^{-1}

k_{des}: rate constant for desorption, s^{-1}

L: liquid mass, kg

m: mass of one molecule, kg

m_A: mass of molecule of component A, kg

m_B: mass of molecule of component B, kg

m_P: mass of dry adsorbent, kg

M: molar mass, kg/kmol

n: molar flux density, mol m^{-2} s^{-1}

n_A: molar flux density of component A, mol m^{-2} s^{-1}

n_B: molar flux density of fluid B, mol m^{-2} s^{-1}

n_i: molar loading of component *i*, mol/g, cm^3 (STP)/g

$n_{i,\,mon}$: monomolecular loading mol/g, cm^3 (STP)/g

$n_{i,\,s}$: molar loading at complete pore filling, mol/g, cm^3 (STP)/g

n_i^{∞}: molar loading at saturation, mol/g, cm^3 (STP)/g

n^0: molar loading of a pure component, mol/g

N: number of molecular layers

p: active pressure, N/m^2

P: total pressure, N/m^2

p_i: partial pressure of component *i*, N/m^2

$p_{i,}$: saturation pressure of component *i* , N/m^2

$(p_{i,}\ s)_r$: saturation pressure of component i at a curved surface, N/m^2

p_0: partial pressure of a pure component, N/m^2

p_t: total pressure, N/m^2

q: volumetric loading of adsorbent, mol/m^3

q: heat flux density, W/K

Q: integral heat of adsorption, J

r: radial distance in microcrystal, m

r_a: external radius of microcrystal, m

r_o: radius of curvature of liquid surface, m

r_p: pore radius, m

R: radial distance in adsorbent particle, m

R: special gas constant, J kg^{-1} K^{-1}

***R*:** universal gas constant (R = 8.31 J mol^{-1} K^{-1})

R_a**:** external particle radius, m

***S*:** solid mass of adsorbent, kg

***S*:** selectivity

***t*:** time, s

***T*:** absolute temperature, K

$u\left(\frac{c}{c_0}, \frac{y}{y_0}\right)$**:** concentration ratio

***U*:** molar internal energy, J/mol

ΔU**:** isochoric heat of adsorption, J/mol

$\dot{v}$**:** volume flux density of fluid, m/s

***V*:** specific adsorbed (liquid) volume, cm^3/g

v_m**:** molar volume, m^3/mol

$\dot{V}$**:** volume flux of fluid, m^3/s

V_c**:** total column volume, m^3

V_m**:** volume of solid phase, m^3

V_s**:** total pore volume, cm^3/g

***x*:** mole fraction of sorbate, mol/mol

***X*:** mass loading of adsorbent, g/g

$X_{m,i}$**:** mass loading of a zeolite crystal with component *i*, g/g

X_i^***:** equilibrium loading of component *i*, g/g

$\overline{X}$**:** mean mass loading of adsorbent, g/g

$\overline{X}_M$**:** mean mass loading of adsorbent in macropores, g/g

***y*:** mole or mass fraction of fluid, mol/mol, g/g

Y_0**:** mass loading of fluid at entrance to fixed bed, g/g

Y^***:** mass loading of fluid at equilibrium, g/g

***Y*:** molar or mass loading of fluid, mol/mol g/g

***z*:** axial distance, m

***Z*:** length of adsorber bed, m

Greek Letters

α**:** heat-transfer coefficient, W m^{-2} K^{-1}

$\overline{\alpha}$**:** total heat-transfer coefficient, W m^{-2} K^{-1}

α_{iv}**:** parameter of nonideality

β**:** affinity coefficient, J/mol

β**:** mass-transfer coefficient, m/s

γ**:** activity coefficient

ϵ**:** adsorption potential, J/mol

ϵ_B**:** voidage

ϵ_p**:** particle porosity

ϵ_t**:** total porosity

η**:** dynamic viscosity, kg m^{-1} s^{-1}, mPa s

θ**:** degree of coverage

θ**:** temperature, °C

λ**:** thermal conductivity, W m^{-1} K^{-1}

Λ**:** free path of molecules, m

μ_p**:** tortuosity factor

ν**:** kinematic viscosity, m^2/s

ξ**:** drag number

π: spreading pressure, J/m^2

π': reduced spreading pressure, cm^3/g

ρ: true density, kg/m^3

ρ_B: bed density, kg/m^3

ρ_p: particle density, kg/m^3

ρ_s: solid density, kg/m^3

σ: surface tension, J/m^2

σ: collision diameter, m

φ: relative saturation

Φ: surface adsorption saturation pressure

Ψ: association parameter

Ψ: porosity of bed, m^3/m^3

τ: time of adsorption, h

Characteristic Numbers

$Bi = \frac{\alpha d}{6\lambda_s}$: Biot number of heat transfer

$Bi' = \frac{R_a \beta \mu p}{3\epsilon_p D_M}$: Biot number of mass transfer

$Fo = \frac{Dt}{r_p^2}$: Fourier number

$K = \frac{\dot{v} Z}{\psi D_{ax}}$: dimensionless number

$Kn = \frac{\Lambda}{2r}$: Knudsen number

$Nu = \frac{\alpha d}{\lambda_s}$: Nusselt number

$u_b = 2 + \sqrt{Nu_{\text{lam}}^2 + Nu_{\text{turb}}^2}$: Nusselt number of single bed

$Nu_{\text{lam}} = 0.664\sqrt{Re_\psi} Pr^{1/3}$: Nusselt number of laminar flow

$Nu_{\text{turb}} = \frac{0.037 Re_\psi^{0.8} Pr}{1 + 2.44 Re_\psi^{-0.1}\left(Pr^{2/3} - 1\right)}$: Nusselt number of turbulent flow

$Pe = \frac{\dot{v} 2R_a}{\psi D_{ax}}$: Péclet number of particle

$Pr = \frac{\nu}{a}$: Prandtl number

$Re_\psi = \frac{\dot{v} 2R_a}{\psi \nu}$: Reynolds number of particle

$Sc = \frac{\nu}{D_{AB}}$: Schmidt number of fluid

$Sh_{fb} = \frac{2R_a \beta}{D_{AB}}$: Sherwood number of fixed bed

$Sh_{\text{lam}} = 0.664\sqrt{Sh_{\text{lam}}^2 + Sh_{\text{turb}}^2}$: Sherwood number of single bead

$Sh_{\text{lam}} = 0.664\sqrt{Re_\psi} Sc^{1/3}$: Sherwood number of laminar flow

$Sh_{\text{turb}} = \frac{0.037 Re_\psi^{0.8} Sc}{1 + 2.44 Re_\psi^{-0.1}\left(Sc^{2/3} - 1\right)}$: Sherwood number of turbulent flow

1. Introduction

The extraction of a protein or peptide from biological raw materials, i.e., *downstream processing*, can be divided into two main steps: *isolation* and *purification*. In the isolation step, a crude product is obtained by techniques such as cell digestion, microfiltration, ultrafiltration, precipitation, or adsorption. The objective is to obtain a fully “clarified” material from which all particulate components have been removed (⟶ Biochemical Separations).

This article is concerned with the second step, i.e., the purification of biomolecules from crude material by means of high-resolution chromatography. It is intended as a guide for the development of an economic purification scheme. A systematic approach is used that simplifies process planning and helps avoid errors. Planning consists of three main steps:

1. development of a logical downstream strategy in the laboratory,
2. optimization of process parameters, and
3. scaling up from the laboratory to the production scale.

Since the development of ion-exchange materials based on cellulose [1] and gel filtration media based on cross-linked dextrans [2], liquid chromatography has become the most important technique in the purification of proteins and peptides.

The introduction of additional separation principles (e.g., affinity chromatography [3]) and of new media based on cross-linked agarose [4] or organic polymers [5] has greatly increased the potential and performance of liquid chromatography. Many biologically active products can be purified chromatographically on a commercial scale. Their number continues to increase, partially as a result of the possibilities offered by genetic engineering. These substances include proteins from natural sources (e.g., plasma albumin) and products of modern biotechnology (e.g., monoclonal antibodies, interferon, vaccines, insulin, growth hormone, and tissue plasminogen activator).

Biological products are often highly active, relatively labile substances that occur in nature in very low concentrations. They must be separated from numerous impurities and are difficult to characterize fully.

The use of high-resolution liquid chromatography is, therefore, justified principally in the “high value – low volume” market, i.e., for the purification of products which are used in small amounts because of their efficacy, but which command high prices (Fig. 1). These are often enzymes, proteins, or peptides with potential use in clinical therapy or diagnosis; some are industrially used proteins with high purity requirements (e.g., proteases, glucose isomerase).

Figure 1. Products separated by process-scale chromatography (adapted from [11] with permission)

Experience with chromatography as a production method for therapeutic agents was gained primarily with insulin [6] and serum proteins [7]; chromatography has been used for their industrial production since the early 1970 s. A number of other substances produced by the human body are potential drugs with good prospects of becoming commercially successful (Table 1). With these highly effective substances, side effects are expected to be largely excluded. Licensing authorities already consider at least one chromatographic step essential for their purification [8]. However, implementation of chromatography on an industrial scale depends on the success of products purified in the pharmaceutical and diagnostic sectors.

Table 1. Chromatographically purified biological products used as human therapeutic agents

Product	Use
Albumin	plasma substitution
Epidermal growth factor (EGF)	wound healing
Erythropoetin	anemia in dialysis patients
Factor VIII	hemophilia
Human growth	growth disorders

hormone (HGH)	
Human insulin	diabetes
Interferons	treatment of cancer and infectious diseases
Interleukin-2	cancer treatment
Monoclonal antibodies (MAb)	cancer treatment and diagnosis, general diagnosis, affinity chromatography
Superoxide dismutase (SOD)	myocardial infarction therapy
Tissue plasminogen activator (tPA)	dissolution of blood clots
Tumor necrosis factor (TNF)	cancer treatment and diagnosis

Additional factors must be taken into account, especially in the development stage. Economic considerations require thorough optimization of parameters such as yield or the dimensioning of a process step. Factors that are not primarily chromatographic are also important, e.g., process hygiene. Finally, detailed process documentation for the control of biological product safety is almost as important as the preparative process itself.

Introduction of these additional aspects means that all sectors of the production process must be analyzed thoroughly and considered in relation to each other. Isolation and purification (downstream processing) can no longer be separated from one another. In addition, selection and treatment of the biological raw material (upstream processing) have far-reaching consequences. Process development thus creates an *integrated process* with a *logical sequence* of coordinated steps.

Because chromatographic purification is always the final step of this integrated process, it is greatly affected by decisions concerning the raw material and earlier steps (isolation and conditioning). The feasibility and elegance of the final purification, together with economic and technical requirements, thus best reflect the standards of the entire process. Criteria for evaluating a production process are listed in Table 2.

Table 2. Criteria for the evaluation of a production process

Criterion	Comments and requirements
Cost	investment costs are governed by product and market; production costs should be as low as possible
Productivity	should be high, with low effort
Product purity	depends on application; high purity has a market advantage
Process time	should be short because of low product stability and minimization of process costs
Execution	should be technically simple and clear (improved process safety, compliance with working time regulations)
Flexibility	necessary because of raw material variations, use of investment for different processes
Documentation	should be as complete as possible for product registration

[Top of Page]

2. Chromatographic Techniques

Various chromatographic methods available for the purification of biological products are summarized in Table 3. (For a detailed description, see ⟶ Basic Principles of Chromatography; ⟶ Enzymes – Chromatography.) Their management on a laboratory scale is described in many textbooks (e.g., [9]).

Table 3. Chromatographic separation methods

Method	Separation criteria	Important parameters
Gel filtration	particle size	column length
Ion exchange	particle charge	pH, ionic strength
Hydrophobic interaction and reversed phase chromatography	hydrophobicity	polarity, ionic strength
Affinity chromatography	biospecific interaction	ligand, eluent

Ion-exchange chromatography (IE) is used in ca. 75 % of all protein purifications; affinity chromatography (A) in ca. 60 %; gel filtration in ca. 50 %; and hydrophobic interaction chromatography (HIC) in ca. 30 % [10]. Reversed phase chromatography (RPC) is of interest virtually only for peptides and small organic molecules. In chromatographic purification sequences, the sample should be passed from step to step without conditioning. This can be achieved if the elution conditions for a given stage correspond to the starting conditions for the next stage. Logical sequences are given in Table 4.

Table 4. Logical sequence of chromatographic steps

Technique	Starting conditions	Elution conditions	Logical sequence	
			before	after
Gel filtration (G)	optional	optional	optional	optional
fractionation or desalting mode *				
Ion-exchange chromatography (IE)	low ionic strength	increased	HIC	HIC, A
fractionation or concentration mode		ionic strength		
Hydrophobic interaction	high ionic	low ionic	IE, A, salt	IE, A
chromatography (HIC)	strength	strength	precipitation	
Affinity chromatography (A)	low or high ionic strength	increased ionic strength, competitive eluent, reduced pH	HIC, IE	IE

* The fractionation mode should only be used as a final step.

2.1. Adsorptive Methods

All chromatographic methods apart from gel filtration utilize the selective adsorption of the sample on the surface of the chromatographic medium. This allows both *fractionation* of the sample and *concentration* of the desired component.

Separation of a mixture of substances involves two steps. First, a fraction of the sample is adsorbed and the nonadsorbed fraction is washed off. The bound components are then eluted by changing the eluent composition. Continuous, usually ionic strength gradients are often used for elution in the laboratory. In large-scale separations, stepwise gradients are generally preferred. However, programmable linear gradients are also being introduced. Their use allows direct scaleup, thereby eliminating a developmental step; fewer elution solutions are required and equipment costs may be lower.

Short columns only 5 – 20 cm long but with a large diameter (5 – 180 cm) are used. This allows very high flow rates of 200 – 400 cm/h, practically complete utilization of capacity, and rapid processing of large volumes. The process cycle time is unnecessarily long with longer columns, which are required only when the separation is carried out under isocratic conditions, i.e., when the composition of the elution buffer remains constant as in reversed phase or, more rarely, ion-exchange chromatography.

The fraction of the gel bed utilized for adsorption varies from 10 % for the separation of two substances with very similar behavior to nearly 100 % for particularly selective conditions.

2.1.1. *Ion-Exchange Chromatography (* ⟶ Ion Exchangers*)*

Many biological molecules possess a net charge whose size and sign depend on pH. This property is utilized in ion-exchange chromatography for selective adsorption onto a carrier derivatized with charged groups. Distinction is made between anion exchangers with positively charged groups (e.g., diethylaminoethyl or quaternary ammonium) and cation exchangers with negatively charged groups (e.g., carboxymethyl, sulfopropyl). The exchangers may be either strong or

weak. Examples are listed in Table 5.

Table 5. Examples of media for ion-exchange chromatography.

Trade name *	Manufacturer
Strong ion exchangers	
Q Sepharose Fast Flow	Pharmacia (Sweden)
S Sepharose Fast Flow	Pharmacia
Fractogel TSK SP-650	Merck (FRG)
QA Trisacryl LS	IBF biotechnics (France)
SP Trisacryl LS	IBF biotechnics
Q Sepharose High Performance **	Pharmacia
S Sepharose High Performance **	Pharmacia
Weak ion exchangers	
DEAE Sepharose Fast Flow	Pharmacia
CM Sepharose Fast Flow	Pharmacia
Fractogel TSK DEAE-650	Merck
Fractogel TSK CM-650	Merck
DEAE Trisacryl LS	IBF biotechnics
CM Trisacryl LS	IBF biotechnics

* Abbreviations: DEAE = diethylaminoethyl; CM = carboxymethyl; Q, QA = quaternary ammonium; S, SP = sulfopropyl; Sepharose Fast Flow = highly cross-linked agarose matrix; Fractogel = hydrophilic vinyl polymer matrix; Trisacryl = hydrophilic acrylic polymer matrix.
** High performance, particle size 34 µm.

Sample constituents bind to the exchanger at low ionic strengths. Between 10 and 100 mg of protein can be adsorbed per milliliter of exchanger. Numerous sample components usually compete for adsorption onto binding sites. Therefore, the binding capacity of an exchanger for the target product may differ very greatly from its theoretical capacity for a pure substance. The strength and selectivity of binding for a given protein are controlled by the initial pH and ionic strength. The actual *dynamic capacity* used under working conditions (i.e., the binding capacity of a given exchanger for a product with given impurities) is governed not only by the pH and ionic strength, but also by the flow rate and matrix properties (see Section Experimental Data). Bound substances are eluted selectively by increasing the ionic strength or changing the pH. Examples of cation- and anion-exchange separations are shown in Figures 2 and 3, respectively. Separation performance can be controlled by the shape of the gradient used.

Figure 2. Purification of immunoglobulin G (IgG) from plasma by cation-exchange chromatography

Elution buffers: a) 0.02 mol/L sodium acetate, pH 6.5; b) 0.01 mol/L glycine, pH 7; c) 0.1 mol/L glycine and 0.15 mol/L NaCl, pH 9.0

Chromatography medium: CM Sepharose Fast Flow; column diameter: 80 cm; bed height: 5 cm; productivity: 1.3 kg of IgG per hour

Figure 3. Purification of albumin from plasma by anion-exchange chromatography

Sodium acetate elution buffers: a) 0.020 mol/L, pH 5.2; b) 0.025 mol/L, pH 4.5; c) 0.15 mol/L, pH 4.0

Chromatography medium: DEAE Sepharose Fast Flow; column diameter: 80 cm; bed height: 5 cm; productivity: 1.7 kg of albumin per hour

Hydrophobic interaction chromatography, affinity chromatography, or gel filtration is best used after ion-exchange chromatography (Table 4).

2.1.2. *Affinity Chromatography*

In affinity chromatography, the product to be purified is specifically adsorbed on an affinity ligand coupled to a matrix. This is analogous to the specific binding processes that are necessary for the biological function of proteins, but with the difference that the immobilized ligands do not undergo subsequent conversion.

Well over 100 different ready-to-use media are available, some examples are given in Table 6. Activated media for in-house production are also being marketed. Many techniques exist, with different starting and elution conditions; their range of applications is wide [12]. They can be divided into three groups according to use:

1. *specific ligands* (e.g., monoclonal antibodies, protein A, enzyme inhibitors) for single proteins [13];
2. so-called *general or group-specific ligands* such as immobilized metal ions [14], and
3. *artificial ligands* such as textile dyes [15].

Table 6. Examples of affinity chromatography media

Trade name	Manufacturer
Group-specific ligands	
Chelating Sepharose Fast Flow	Pharmacia (Sweden)
Lysine Sepharose Fast Flow	Pharmacia
Specific ligands	
Protein A Sepharose Fast Flow	Pharmacia
Heparin Sepharose	Pharmacia
Artificial ligands	
Avidin Ultrogel A4R	IBF biotechnics (France)
Blue Sepharose Fast Flow	Pharmacia
Matrex Gel Blue A	Amicon (USA)
Blue Trisacryl M	IBF biotechnics
Fractogel TSK AF Red	Merck (FRG)
Fractogel TSK AF Phenylboronate	Merck

Because of the high selectivity of affinity media, very large volumes of dilute product solutions can be processed. The capacity of the gel is not reduced by the binding of numerous foreign proteins, which occurs with ion-exchange or hydrophobic interaction chromatography.

Purification factors of well over 1000 can be achieved with affinity chromatography, although the mean enrichment obtained in practice is only ca. 100-fold [10]. Higher values can often be achieved only with relatively impure samples.

The sample mixture is generally applied to the column at low ionic strength and in the neutral pH range. After nonbound impurities are washed out, the product can be eluted by using a gradient of increasing ionic strength or by reducing the pH.

A further increase in selectivity can be achieved with product-specific eluents which compete with the product for binding to the matrix. In favorable cases, a product can be purified to homogeneity in one or two steps with the aid of affinity chromatography. Figure 4 shows the one-step purification of monoclonal antibodies with Protein A Sepharose. (Protein A is a bacterial protein that contains high-affinity sites for immunoglobulin G and is used as a ligand for purifying antibodies.)

Figure 4. Purification of monoclonal antibody 2 b from mouse ascites fluid by affinity chromatography

a) Sample: 50 mL of mouse ascites fluid diluted 1 : 2 with phosphate-buffered saline (PBS), pH 8.0; b) Eluent: PBS, pH 6.0; c) Eluent: PBS, pH 5.0

Chromatography column (1.6×5 cm) containing 10 mL of Protein A Sepharose CL-4 B. Results published courtesy of A. LARSSON, Pharmacia.

2.1.3. *Hydrophobic Interaction Chromatography*

Most proteins (not only “hydrophobic” proteins) possess hydrophobic regions on their surface which allow interaction with a hydrophobically derivatized matrix in aqueous surroundings. The forces responsible for adsorption to a carrier material of this type depend on the increase in entropy arising from the displacement of hydrophobic molecular regions from the polar surroundings [16]. These forces are increased at high salt concentrations (salting out).

Phenyl, butyl, and octyl residues are the common ligands used in HIC (Table 7). The hydrophobic properties of phenyl matrixes are suitable for purifying most proteins under mild conditions.

Table 7. Examples of media for hydrophobic interaction chromatography

Trade name	Manufacturer
Phenyl Sepharose Fast Flow	Pharmacia (Sweden)
Octyl Sepharose CL-4B	Pharmacia
Fractogel TSK Butyl	Merck (FRG)

Hydrophobic interaction is affected by the action of specific salts or the polarity of the solvent [9], [17]. Proteins can be adsorbed by a hydrophobic matrix at high salt concentrations, and nonbound material can be washed away. The bound substances are then eluted selectively with decreasing polarity in a second step. Decreasing salt gradients are used generally, but further reduction of polarity by addition of nonpolar organic solvents such as ethanediol may be necessary (Fig. 5).

Figure 5. Purification of colony stimulating factor CSF-1 from human urine by hydrophobic interaction chromatography (published with permission [47])

Elution buffers: a) – e) Phosphate-buffered saline containing decreasing concentrations of NaCl (mol/L): a) 4; b) 3; c) 2; d) 1; e) 0.5; f) 4 mol/L guanidine · HCl in 10 mmol/L NaOH containing 4 mol/L 20 vol % ethanol

Sample: 500 mL of concentrated human urine containing 4 mol/L NaCl; chromatography medium: Phenyl Sepharose CL-4 B; column dimensions: 5×22 cm; flow rate: 15 cm/h

Chromatographic techniques using low ionic strength as the starting condition can be utilized after HIC (Table 4).

2.1.4. *Reversed Phase Chromatography*

Hydrophobic interactions are also utilized in reversed phase chromatography (RPC). However, whereas HIC is a nondenaturing method, proteins are usually denatured by the nonpolar solvents used for elution from the highly hydrophobic RPC matrices [18]. Examples of RPC media are Lichrosorb and Lichroprep (Merck, Federal Republic of Germany), and Matrex silica gels (Amicon, United States). The preparative use of RPC in biotechnology is thus limited to the fractionation of substances such as antibiotics (Fig. 6) and synthetic or physiological peptides [19] up to about the size of insulin, M_r 5800. The use of RPC together with gel filtration and ion exchange has already proved to be of value in the production of peptides such as oxytocin and vasopressin [20].

Figure 6. Reversed phase chromatography of a cephalosporin C fermentation broth (published with permission [11])

Chromatography medium: $PREPC_{18}$ column: 6×2 ft segment; mobile phase 97.5 parts of 20 mmol/L ammonium acetate (pH 5.2), 2.5 parts of acetonitrile; flow rate: 1 L/min; injection volume: 16 L containing 4.5 mg/mL cephalosporin C

Because of the particularly good selectivity of RPC, very high resolution can be obtained. Future developments may produce RPC materials which, unlike conventional silica-based materials, are more suitable for industrial production processes. Silica materials are not alkali-stable and often have poor batch-to-batch reproducibility.

2.2. Gel Filtration

In gel filtration, a porous matrix is used to separate a mixture of substances according to their molecular mass and shape. The size range in which resolution can be achieved is determined by the pore size of the matrix. Large molecules do not enter the pores and are eluted quickly. Small molecules enter the pores and move through the column more slowly. Molecules are thus eluted in order of decreasing molecular mass. Ideally, adsorption of sample constituents does not occur.

Gel filtration is used for *fine fractionation* of individual substances, e.g., separation of monomers and oligomers. The fine fractionation of immunoglobulin G (IgG) is shown in Figure 7. Media with a separation range that includes the molecular masses of the substances to be separated are employed (Table 8).

Table 8. Examples of gel filtration media

Trade name	Separation range, M_r	Manufacturer	Gel matrix polymer
Sephacryl S-100 HR	1000 – 100 000	Pharmacia (Sweden)	dextran – acrylamide
Sephacryl S-200 HR	5000 – 250 000	Pharmacia	dextran – acrylamide

Sephacryl S-300 HR	10 000 – 1.5×10^6	Pharmacia	dextran – acrylamide
Sephacryl S-400 HR	20 000 – 8×10^6	Pharmacia	dextran – acrylamide
Fractogel TSK HW-55	1000 – 1×10^6	Merck (FRG)	hydrophilic vinyl
Fractogel TSK HW-65	50 000 – 5×10^6	Merck	hydrophilic vinyl
Trisacryl GF 2000 LS	10 000 – 15×10^6	IBF biotechnics (France)	hydrophilic acrylic
Sephadex G-25 *	1000 – 5000	Pharmacia	cross-linked dextran
Bio-Gel P-2 *	100 – 1800	Bio-Rad (USA)	acrylamide
Matrex Cellufine GH 25 *	200 – 2000	Amicon (USA)	silica based
Trisacryl GF 05 LS *	200 – 2500	IBF biotechnics	hydrophilic acrylic
Sepharose 12 prep grade **	1000 – 300 000	Pharmacia	highly cross-linked agarose
Superdex 75 **	3000 – 70 000	Pharmacia	agarose – dextran

* Media for desalting – rebuffering,
** High-performance media, particle size 34 µm.

Figure 7. Separation of immunoglobulin G (IgG) oligomers from a previous ion-exchange step by gel filtration (final step in purification of monoclonal antibodies)

Chromatography medium: Sephacryl S-200 HR; column diameter: 11.3 cm; bed height: 100 cm; eluent: 0.05 mol/L Tris – HCl, 0.15 mol/L NaCl, pH 7.5; flow rate: 7.5 cm/h

When gel filtration is used to separate salts from macromolecules (*desalting* or *rebuffering* of a protein sample), only *group fractionation* is achieved. This technique is an alternative to ultrafiltration or diafiltration. Gel filtration media suitable for desalting have a fractionation range for molecules with molecular masses below 5000 (Table 8).

In gel filtration, only the pore volume of the particles packed in the column is available for separation, so sample volumes are limited. The upper protein concentration limit depends on the viscosity, the viscosity of the sample should not be more than twice that of the elution solvent.

The possible sample volume per cycle is restricted to about 5 % of the column volume in fine fractionation and to ca. 15 – 30 % in desalting. Column lengths ranging from 60 cm (desalting mode) to 180 cm (fractionation mode) and diameters of 5 – 180 cm are used. Flow rates are generally 3 – 15 cm/h for the fractionation mode and 100 – 200 cm/h for the desalting mode.

Gel filtration always leads to rebuffering if the compositions of the sample and the eluent differ. Consequently, irrespective of sample composition, gel filtration can be combined with all other chromatographic techniques or can be used as a conditioning process for the next step (Table 4).

Gel filtration in the desalting mode can be applied with high productivity at any processing stage. In the fractionation mode, it can be used economically only as a final, fine purification step (separation of polymers) due to its relatively low volume capacity. Formulation of the product is also achieved this way.

[Top of Page]

3. Downstream Strategy

All preparative steps must be logically coordinated, and subsequent processing must be taken into account in selecting raw materials (cf. Chap. Introduction). The present chapter describes the correct strategy for an integrated preparative process. The main factors considered are:

1. minimization of the number of process steps required,
2. optimal preparation of the raw material, and
3. development of a chromatographic purification system.

3.1. Number of Preparative Steps

Product yield decreases with the number of preparative steps (Fig. 8). Each additional step also increases production time and, thus, processing cost. Therefore, the number of steps must be kept as small as possible. The target product can generally be purified in two or three chromatographic steps.

Figure 8. Overall product yield as a function of the number of process steps

Percentage yields for individual steps: a) 95; b) 90; c) 85; d) 80

However, an important exception to this rule may occur when a very complex, perhaps more expensive, step replaces several simple ones. In this case, preference might be given to another rule: the process should be kept as simple as possible.

A number of ways are available for simplifying processing and for minimizing the number of steps (Table 9). The raw material should be selected and optimized in such a way that the product is easy to isolate and impurities are kept at a minimal level (Section Preparation of an Optimal Raw Material). The crude product should be optimally conditioned for the first purification step. Subsequent chromatographic steps should be arranged in a logical sequence (Section Logical Sequence of Chromatographic Steps). Each step should be optimized to make full use of the separation performance of the method used (Chap. Optimization). Only necessary processing should be performed. The degree of purity required does not always have to be the maximum purity achievable by chromatography. In some cases, characterization of the residual impurities and demonstration of their “harmlessness” are sufficient.

Table 9. Integration of chromatography and accompanying operative steps

Operative step	Parameters affected by operative step
Selection of raw material	1) product concentration
	2) product accessibility (is cell disruption necessary?)
	3) number and type of impurities (can protease content be decreased?)
	4) batch-to-batch variation
Genetic engineering of raw material	1) product concentration (can it be increased?)
	2) product accessibility (can it be improved?)
	3) number and type of impurities (can protease content be lowered?)
	4) reproducibility (can stability of cloned gene be guaranteed?)
	5) product safety (effort required for removal of foreign DNA)
Cell culture	1) scale of final purification (continuous culture allows a reduced scale)
	2) number and type of impurities (can they be reduced by modifying the culture medium?)
Isolation, conditioning	1) lifetime of gel media (clarification of product solution)
	2) efficiency of first chromatographic step (adjustment of pH, ionic strength, protein concentration)
	3) product yield (minimization of mechanical stress, protease content, number of steps)

3.2. Preparation of an Optimal Raw Material

As a result of advances in genetic engineering, proteins and peptides are increasingly being produced by genetically modified cells that can be cultivated in fermentors. The cost of fermentation is a highly significant factor in the calculation of production costs. Thus, the product must be isolated from the fermentation broth in maximum yield. The resultant product solution should be fully clarified, particle-free, and preferably sterile-filtered, i.e., a suitable raw material for chromatographic purification [21].

Choice and Treatment of the Raw Material. Raw materials may be either natural or tailor-made.

Natural materials have specific properties that cannot be changed: availability, product content, contamination with secondary materials, and risk factors. An example is human serum used for the production of albumin, clotting factors, and other plasma proteins [7]. The preparation of natural materials must be adapted to the given conditions.

Tailor-made materials can be modified easily. Availability, product concentration, and impurities can be controlled within wide limits. Genetic engineering [22], the hybridoma technique [23], or combinations of both (chimeric antibodies) can be used to modify the chemical structure of a product to improve its action or eliminate side effects. Raw materials include genetically engineered bacteria, yeasts, or mammalian cells, as well as hybridoma cells.

Table 10 is a survey of the potential advantages and disadvantages of various producer cells and organisms (see also [41]).

Table 10. Advantages and disadvantages of productive cells [24]

Cells	Advantages	Disadvantages
Bacteria	1) cell culture well mastered	1) pathogenicity
	2) many genetic "tricks" possible [25], [26]	2) protein glycosylation not possible *
	3) inclusion bodies protect against proteolysis [27]	3) product contamination by foreign DNA and viruses
	4) high productivity [28]	4) inclusion bodies difficult to process
Yeasts [29]	1) cell culture well mastered	1) different glycosylation pattern from mammalian cells
	2) hardly any endogenous protein secretion [30]	
	3) secretion can be partially controlled genetically [31]	
	4) no endotoxins, safe organisms	
Fungi [32], [33]	1) cell culture well-mastered, simple culture media	1) different glycosylation pattern from mammalian cells
	2) safe organisms (*Aspergillus niger*)	
	3) high productivity, used for industrial enzymes [34]	
Insect cells [35]	1) baculovirus as vector with good expression system	1) posttranslational modification not clear
	2) high productivity [36]	2) costs similar to mammalian cells [36]
Mammalian cells [37], [38]	1) posttranslational modification, correct glyco-sylation [39]	1) genetic instabilty, oncogenicity
		2) sensitivity of cells
	2) cell immobilization, e.g., with microcarriers [40]	3) slow growth, low cell density
	3) continuous perfusion, removal of proteases	4) relatively low productivity, high cost

* Many proteins require correct posttranslational glycosylation to perform their functions.

Isolation of Cell Products. The target product must be isolated from its natural surroundings to allow further purification. The steps required for this are governed largely by the nature of the raw material and the localization of the product (intra- or extracellular).

Intracellular products occur in the cytoplasm (perhaps in the form of inclusion bodies) or in the periplasmic space. Harvested cells must be disrupted and particulate components removed by one or two centrifugation steps and microfiltration. In the case of inclusion bodies, refolding of the product must be achieved. Conditioning of the fermentor broth by addition of flocculants or filtration aids, by heat treatment, or by pH adjustment may also be necessary.

Table 11 summarizes the techniques used for preliminary isolation of intracellular products. Many isolation methods are problematic due to the mechanical stress imposed on the product and difficulty in scaling up.

Table 11. Isolation of cell products

Objective	Technique	Advantages	Disadvantages
Product release	cell disruption [9], [42]	none	mechanical stress
Clarification	centrifugation [38]	none	aerosol formation, scaleup difficult
	microfiltration [43]	simultaneous removal of bacteria	short membrane lifetime
Concentration	ultrafiltration [44],	simultaneous	high costs, system

	[45]	sterilization	difficult to optimize
Preliminary purification (salts, proteases, nucleic acids)	precipitation	none	high costs, environmental contamination
	adsorption [46]	simultaneous use of selectivity for removal of contaminants	maintenance can be laborious
Lipid removal	defatting	none	low product yields, environmental contamination

Techniques for greatly simplified isolation have also been developed for nonsecretory systems. Proteins have been successfully extracted in two-phase systems used for processing cell homogenates (⟶ Biochemical Separations [48]). If Phenyl Sepharose is added to the system, the proteins can be adsorbed and simultaneously protected against the action of proteases [21]. With this combination, the crude material can quickly be prepared for final purification.

Extracellular products are secreted into the medium so that the cells need only be filtered off, possibly continuously. This offers advantages in terms of time and yield. A secretion system also seems to be useful in avoiding the technical problems listed in Table 11. However, special regulatory aspects must be considered when running a continuous cell culture [49].

In favorable cases, continuous adsorption onto a chromatographic medium can be used, which leads to rapid separation of critical contaminants such as proteases that might digest the secreted product. Unter certain circumstances, classical isolation steps can be avoided completely (see Chap. Developments). As a result of the simultaneous concentration effect, all further steps can be undertaken on a significantly smaller scale saving both time and costs.

Product Stabilization. The isolated product requires specific conditions if it is to remain stable for long periods. Optimal ionic strength, pH range, and concentration of added stabilizers (e.g., trace elements) must be determined and adjusted in the crude product. Protease activity can be controlled to some extent by keeping the temperature as low as possible. Organic solvents or special additives such as protease inhibitors should be avoided because their later removal causes problems. Foaming should be inhibited to prevent denaturation.

3.3. Development of a Chromatographic Purification System

An individual purification system must be determined for each biological product. A screening process is used to select appropriate chromatographic methods. The choice of a chromatographic material is determined not only by the "chromatographic criteria" applied during screening (Section Screening of Chromatographic Methods (Method Scouting)), but also by "non-chromatographic marginal conditions." Examples of the latter are process hygiene measures and the scale of production, which dictate requirements such as the physical and chemical stability of gel media. Chromatographic techniques are combined to give a logical sequence with only a few steps (Section Logical Sequence of Chromatographic Steps).

All developmental work must be carried out on the smallest suitable scale in the laboratory to save time. Usually, each step is then rechecked and conditions are optimized (fine tuning). This may be done after the process is implemented in the pilot plant where significant amounts of the substance are produced for toxicological or clinical studies. Nevertheless, optimization should be continued to achieve the smallest scale of production possible. Optimization is discussed in Chapter Optimization. Table 12 gives a scheme of tasks allocated to each operational unit involved in process development.

Table 12. Allocation of tasks in the development of an industrial chromatographic purification process

Operational unit	Tasks listed in chronological order
Research and development	1) development of analytical methods
	2) screening of possible purification methods
	3) choice of suitable separation media according to separation performance, dynamic capacity, chemical stability (lifetime, process hygiene), mechanical stability (handling on a production scale), and current documentation *
	4) development of a purification plan
	5) optimization of each step according to productivity, required purity, product safety (removal of DNA, toxins, etc.), and adaption to changes after scaling up the cell culture

	6) full documentation of procedure
Pilot plant	1) scaling up process: requires modification due to column features and longer storage time for intermediate products
	2) manufacture of experimental amounts of product
	3) process automation
	4) development of manufacturing instructions including handling of separation media, sterilization, pyrogen removal, quantitative data for dimensioning
Production plant	1) planning and construction of a production plant fulfilling the requirements
	2) production and on-site analysis work
	3) process validation, batch documentation

* Instructions given in the literature can generally be extrapolated to the equivalent separation media suitable for industrial use (e.g., instructions for DEAE cellulose can be used for DEAE Sepharose Fast Flow).

3.3.1. *Screening of Chromatographic Methods (Method Scouting)*

The “chromatographic” criteria for gel selection are studied by testing a number of gels and buffer solutions for ion-exchange, affinity, hydrophobic interaction, or gel filtration chromatography. Parameters such as the nature of the groups coupled to the matrix or the gel porosity are selected together with provisional conditions such as pH, loading, and flow rate. Precise conditions are determined during subsequent optimization when the gel and the sequence of processing steps have been selected (see Chap. Optimization).

3.3.1.1. *The Gel Bank*

Methodological screening is best carried out with the aid of a *gel bank*, which is a collection of different chromatographic media. The media are stored ready-for-use in small, perfectly packed (1 – 50 mL) columns; their packing quality can be tested. Only materials with physical and chemical stabilities suitable for production processes should be used, examples are given in Table 13. The preliminary selection of gel media is based on the best possible linear flow rate and on nonchromatographic criteria such as expected lifetime and process hygiene.

Table 13. Examples of chromatographic media suitable for industrial processes

Chromatographic method	Medium	CIP * using sodium hydroxide, mol/L
Gel filtration	Sephacryl S-100 HR, S-200 HR, S-300 HR	0.5
	Sephadex G-25 c, m, f, sf	0.5
	Fractogel TSK HW-55, HW-65	1
Ion exchange	Q Sepharose Fast Flow	2
	S Sepharose Fast Flow	2
	DEAE Sepharose Fast Flow	1
	CM Sepharose Fast Flow	1
	Fractogel TSK SP-650, DEAE-650, CM-650	1
Hydrophobic interaction	Phenyl Sepharose Fast Flow	1
	Fractogel TSK Butyl	no data available
Affinity	Chelating Sepharose Fast Flow	1
	Arginine Sepharose 4 B	0.5
	Protein A Sepharose Fast Flow **	no data available
	Fractogel TSK AF Red, AF Phenylboronate	no data available

* Cleaning in place.
** Medium with a labile ligand, maintenance using other washing procedures [50].

Modern media with better mechanical and chemical stability, and higher productivity than those required in the laboratory are expensive but may allow considerable savings when used on a production scale. Although cheaper materials can also give the desired separation, they may incur considerable costs, mainly as a result of more laborious regeneration and much shorter lifetime.

The major requirements of the gel material can be deduced from the criteria listed in Table 2.

A *high dynamic capacity* contributes to faster production at lower cost and is favored by the following factors:

1. low linear flow rate,
2. large pore diameter,

3. low sample concentration,
4. high diffusion constant of the sample,
5. high binding rate constant,
6. small gel particle diameter, and
7. low competitive binding of other sample constituents.

The last aspect implies high selectivity, which is the most important factor in designing a high dynamic capacity. Aspects 1 and 3 of course compromise productivity. Thus, a balance has to be found. It is inadvisable to choose a gel material with a high dynamic capacity at only a very low flow rate or sample load.

Good physical stability allows easy packing of the gel in large columns, without deterioration of the separation performance and packing quality achieved in the laboratory. The high flow rates (200 – 400 cm/h) obtained in the laboratory can thus also be used on a production scale.

High chemical stability, especially to sodium hydroxide (0.5 – 2 mol/L, Table 13), is a prerequisite for sterilization and the removal of pyrogens and other contaminants from the packed column (cleaning in place, CIP). Chemical stability is also the best general indicator of the lifetime of a gel under processing conditions.

Modern gel media with *a long predictable lifetime* can be considered part of the column and thus are capital investments rather than consumables. Far more than 100 cycles can be expected of ion exchangers, even after repeated regeneration and cleaning in place (Fig. 9). Some affinity media that utilize proteins as ligands are exceptions; they can be used for only a limited period because they are not stable to rigorous cleaning procedures.

Figure 9. Separation performance of an ion-exchange column after 100 CIP cycles

a) NaCl concentration of eluent; b) Initial chromatogram; c) Chromatogram after 100 cycles;

Chromatography medium: Q Sepharose Fast Flow; sample: 2.5 mg transferrin, 5 mg ovalbumin, 5 mg β-lactoglobulin in 0.5 mL; column diameter: 1 cm; bed height: 4.5 cm; gradient volume: 83 mL; eluent: 20 mmol/L piperazine, pH 6.0; flow rate: 24 mL/h

The *long-term availability* of large amounts of chromatographic media with little batch-to-batch variation guarantees that the process can be carried out reproducibly for as long as required.

Extensive documentation, i.e., Product Master Files, on the chromatographic media and analytical methods supplied by the manufacturer for initial control should facilitate both product registration and regular control checks for the user.

General requirements also apply to the *gel matrix properties:*

Low nonspecific interaction of the gel matrix with sample constituents increases yields and simplifies handling of the material. For proteins, the matrix should have hydrophilic properties; suitable gels are based on cross-linked agarose, dextran, hydrophilic vinyl polymers, or polyacryl-amide.

High matrix porosity or decreased gel bead diameter improves separation kinetics and shortens the total process. Materials are available with bead diameters of ca. 10, 30, and 90 µm (see Tables 5 and 8).

High-Performance Media in the Gel Bank. Particle diameter is misused as a criterion to distinguish high-performance liquid chromatography from conventional liquid chromatography. High-performance gels are considered to have a particle diameter of 30 µm or less. Column efficiency (measured as the number of theoretical plates *N*) and separation kinetics can indeed be improved by using smaller particles. However, in process-scale chromatography, use of the largest possible particle diameter for the desired separation is preferred because it minimizes the resulting counterpressure and thus reduces running costs [51]. Above a certain level, very little is gained by a further increase in column efficiency [52].

Thus, high performance in preparative chromatography is defined by increased productivity that is obtained by optimizing the selectivity of each step (Fig. 10), rather than by increasing the efficiency *N* (selectivity is described in Selectivity). This is achieved by choosing the correct pH in ion exchange, the correct ligands in affinity chromatography, or the correct pore distribution in gel filtration [52].

Figure 10. Relationship of selectivity (α), resolution (R_S), efficiency (*N*, number of theoretical plates), and productivity (published with permission [52])

Productivity is improved more by increasing the selectivity than by increasing the efficiency.

In addition, because of their relatively low matrix content, media with large particle diameters (>30 µm) often show higher porosity, less nonspecific adsorption, and a greater capacity for product loading than do media with small particle diameters (<30 µm). High-performance media often have a lower capacity than conventional media because less room is available on the highly cross-linked matrix for derivatization with charged groups or affinity ligands, and the porosity is not optimal for use with macromolecules.

The gel bank should thus include primarily materials with particle diameters around 90 µm. Particles of 30 µm are useful and, in some cases, indispensable for final polishing or for difficult separation problems. They require more complex apparatus if high flow rates are used because a high counterpressure is produced. A gel bank that includes 30 and 90 µm particles can solve almost all separation problems.

However, particles of 10 µm are used in very small columns for particularly rapid process development. Other materials with larger particle diameters must then be available to which the results can later be transferred as soon as the scale is increased. The appropriate conversion factors must be known. With ion exchangers, the gels must all have the same charged groups, and the influence of different charge densities must be determined in advance experimentally (see Section Transfer Protocol). This is the manufacturer's task. For gel filtration media, the selectivity curves must be identical.

Columns from the gel bank can be run in an automated medium-pressure chromatography system that works with all types of media and particle sizes (Fig. 11). The testing of materials and their related conditions is facilitated by the small scale and automation.

Figure 11. An automated medium-pressure chromatography system

3.3.1.2. *Experimental Data*

Many biological substances of interest for industrial production are described in the literature and have been purified or enriched by chromatography. Extensive reference lists are available [53]. Published methods may be suitable for initial experiments but are often inappropriate for a production process.

Sample Material. For a systematic approach, the sample material must be thoroughly characterized to determine which techniques should be used in screening. The molecular masses, isoelectric points, and titration curves of the product solution obtained in each purification step can be determined by rapid, automated electrophoresis (Fig. 12). Chromatographic titration curves can also be obtained. These data often provide important information for choosing a technique and for determining suitable separation conditions [54]. It is worthwhile to characterize impurities such as proteases, lipids, DNA, and endotoxins carefully. Additional help is obtained by considering the logical sequence of chromatographic steps (Section Logical Sequence of Chromatographic Steps).

Figure 12. Titration curves of three proteins (a, b, and c)

Optimal pH for separation is 9.0 because the difference in net charge is greatest at this point.

Product yield and degree of purification must be determined at each step to evaluate results and compare alternative methods.

The viscosity, primarily a result of high protein and nucleic acid concentrations, should not be greater than ca. 40 N s m^{-2}. If higher, it must be reduced by dilution to avoid increased pressure in the column. Operations should be carried out at room temperature if possible because the viscosity increases and the flow rate decreases at cold-room temperatures of 4 –10 °C.

Gel Media. Guidelines regarding parameters such as flow rate range or height of gel bed can be obtained from the gel manufacturer's product specifications.

Dynamic capacity is a measure of the degree to which adsorbents can be loaded under process conditions and must, therefore, be determined with the original sample in each gel used, as described in [55], [56]. However, guidelines for loading are available for gel filtration (see Section Gel Filtration), and published data may also be usable for adsorption techniques.

The pH of the starting buffer in ion-exchange chromatography should not be more than one pH unit higher or lower than the isoelectric point of the desired product. This ensures that the greatest possible number of impurities either are not bound or can be removed by selective elution. The dynamic capacity for product adsorption is thus maximal. For most applications the pH selected should be kept constant during the separation process; adsorption and elution are then controlled by adjusting the conductivity. A pH value is chosen at which the product just binds but impurities are largely washed away.

In affinity chromatography, screening is often tedious because the choice of gel is difficult if published data are not available. Materials with a broad spectrum of applications are recommended as starting materials, e.g., lysine, chelating, or dye gels. Preactivated gels for in-house synthesis are available if a highly specific affinity medium is required. Optimized affinity media with special matrices, ligands, or ligand concentrations can also be obtained as tailor-made products.

Gel filtration is used for fine fractionation at the end of a purification scheme (see Section Logical Sequence of Chromatographic Steps). The main purpose of screening is thus to find the gel with the best selectivity in the desired separation range of molecular masses. Particular attention should be paid to adsorption effects. The separation range for the desalting mode is predetermined, and the number of possible gel materials is restricted. The choice is based on the productivity desired and on general production requirements.

3.3.2. *Logical Sequence of Chromatographic Steps*

Requirements relating to purification techniques and gel materials are based on the experimentally determined composition of the sample. Conversely, each chromatographic technique requires that the sample fulfills specific, known requirements. Furthermore, each separation step produces a new sample whose properties are determined by the chromatographic technique used and are thus partly predictable.

The interdependence of the sample and the separation techniques means that each purification scheme can be planned to a large degree to develop an effective, integrated process. Individual steps should be combined in a logical, coordinated sequence; the logical position and function of the various steps are summarized in Table 14.

Table 14. Logical position of chromatographic separation methods in purification sequences

Method	Operating mode	Volume capacity	Productivity *	Logical position	Function
Gel filtration	fractionation	low	low **	final step	final purification and formulation
	desalting	moderate	high	optional	conditioning (but a logical se-quence avoids frequent condi-tioning)
Ion exchange	concentration	very high	very high	starting step	reduction of volume, removal of critical contaminants
	fractionation	high	high	optional	fine purification, final purifi-cation
Hydrophobic interaction	fractionation	high	high	starting step, intermediate steps	removal of critical contami-nants, fine purification
Affinity	fractionation	very high	very high	optional, depends on technique	fine purification, final purifi-cation, removal of critical contaminants

* See Section Purpose of Optimization.
** But see Section Optimization of Gel Filtration.

3.3.2.1. *Selection Criteria*

A biological product must almost always be purified in several steps. A sequence of chromatographic methods utilizing several different separation principles (e.g., hydrophobicity, charge, and biological specificity of the product) is advisable.

Individual techniques should follow each other so that the sample can pass from one purification step to the next without intermediate conditioning steps such as concentration by ultrafiltration or rebuffering by gel filtration (Table 4). Appropriate starting conditions for each subsequent step should be achieved by simple means such as dilution, addition of salts, or pH adjustment. Separate concentration steps can easily be avoided because large volumes can be purified and concentrated in one stage with adsorptive techniques (Table 14).

Sample volumes should be reduced quickly during the early steps. Impurities that reduce yield or shorten gel life should be removed at an early stage. An example is the preparation of monoclonal antibodies from cell perfusion systems [57].

If intermediate conditions adversely affect product stability, the step in question must be carried out quickly and the product must be restabilized, e.g., in affinity chromatography of monoclonal antibodies using Protein A Sepharose.

For reasons of cost, high performance techniques using gel materials with particle diameters of ≤30 µm (Section The Gel Bank) should be used only at the end of a purification scheme. Small columns can be employed in the last step in which contaminants harmful to the gel are no longer present.

The definitive choice of a technique is made after coordination of sample properties, chromatographic method, and gel characteristics. Important properties of a sample are its total volume, protein and product contents, ionic strength (conductivity), pH, and viscosity (Table 15). Important properties of a chromatographic method (Tables 4 and 14) are the

binding capacity for the sample in terms of both mass and volume; the ionic strength required for effective loading; and gel properties such as flow rate or stability to stress caused by the sample.

Table 15. Preparation of sample for the first chromatographic step

Parameter	Numerical value	Starting step	Conditioning required
Product concentration	>1 g/L	1) adsorption (fractionation mode)	adjustment of conductivity (e.g., by using a desalting step)
	<1 g/L	2) adsorption (concentration mode)	adjustment of conductivity (e.g., by further dilution)
		3) ultrafiltration	none
Viscosity (total protein)	>40 N s/m^2	1) adsorption	dilution
Conductivity	>5 mS/cm	1) ion exchange	dilution (product concentration ca. 10 mg/L)
		2) gel filtration (desalting mode)	desalting (product concentration 1 g/L)
		3) ultrafiltration	none
		4) hydrophobic interaction chromatography	salt addition, e.g., after precipitation or ion exchange
pH		1) ion exchange	pH adjustment (also stabilizes biological activity)

Choice of the initial step is especially complex and is, therefore, discussed separately (Section The Starting Step) from subsequent steps (Section Subsequent Steps).

3.3.2.2. *The Starting Step*

The choice of the starting step has a decisive effect on process economics because product losses are greatest at this stage.

Sample preparation for the first chromatographic step is summarized in Table 15. Two methods exist for preparing crude products for ion exchange and other techniques requiring low conductivity (including affinity chromatography):

1. If the product is present at very low concentration (≤10 mg/mL), the sample can simply be diluted further.
2. If the product is present at high concentration (ca. 1 g/L), gel filtration can be used for desalting [58]. This is advantageous because not only is conductivity decreased, but small charged molecules that would later reduce the available capacity of an ion exchanger can also be separated [46].

The largest volumes and amounts of protein must be processed in the first purification step. This step should be completed quickly to remove destructive proteases. A large decrease in total volume should be obtained so that the dimensions of subsequent steps and thus costs can be reduced. Consequently, only adsorption methods are usually considered. In some cases, however, desalting or rebuffering by gel filtration may be advantageous (see above); however, this leads to slight dilution and an adsorptive concentration step must follow.

The sample often contains components (e.g., lipids, nucleic acids, or pyrogens) that contaminate the gel material and may reduce its capacity for the product. In affinity media with protein ligands, dangerous contaminants also include proteases. Consequently, the gels used at the start are usually robust materials that can be regenerated even after the heaviest contamination.

Affinity chromatography offers the maximum selectivity and a high capacity for the product, with little interference from foreign proteins. Therefore, it is often chosen as the starting step. Some affinity matrices, such as Chelating Sepharose [59], Lysine Sepharose, or Arginine Sepharose, possess a broad spectrum of applications and are relatively inexpensive. They have been used successfully at the start of purification procedures [60]. The simple ligand in these gels is chemically stable and coupled to the matrix in such a way that the material can be regenerated and sterilized even after heavy sample loading. Samples with high salt content can also be processed by chromatography with immobilized metal ions (Chelating Sepharose).

However, many affinity media are relatively labile and thus unsuitable for the initial step. Prior ion-exchange or hydrophobic interaction chromatography then offers some advantages, despite a possibly lower selectivity.

Ion-exchange chromatography with anion exchangers allows lipids, nucleic acids, and even bacterial endotoxins (lipopolysaccharides) to be bound more strongly than many proteins. These contaminants can thus often be removed from large volumes of crude material and the product can be concentrated simultaneously. Despite the resultant heavy contamination, modern ion exchangers have prolonged lifetimes. Proteases and other impurities can then be removed in the subsequent step, possibly even with the same ion exchanger but with different conditions, e.g., fractionation mode.

Thus, ion-exchange chromatography is by far the most common starting method for purification. The ionic strength of material from cell cultures or natural products is usually so high that conductivities markedly above 5 mS/cm are measured in the crude product (Table 16). The binding of products with conductivities above 5 mS/cm to an ion exchanger presents problems if, as is desirable for selective separation, the working pH is close to the isoelectric point (Section Experimental Data). The ionic strength is thus usually reduced (see above).

Table 16. Approximate conductivity of cell cultures and natural products [61]

Material	Conductivity, mS/cm
Tissue, plasma, body fluids, animal cell culture medium	15
Bacterial cultures	30
Yeast cultures	20

Depending on selectivity, distinction is made between the concentration mode and the fractionation mode in ion-exchange chromatography. If product concentration is very low (≤10 mg/L), the *concentration mode* is used; here, conditions are chosen such that the sample binds strongly and rapidly to the carrier even at very high flow rates (200 – 400 cm/h) where selectivity may be reduced [62]. The product can then be concentrated to a small volume at a lower flow rate (10 – 50 cm/h). Reversing the direction of flow is often advisable to achieve a higher concentration [63].

With higher product concentrations (>10 mg/L), significant purification can be achieved even in the starting step. The *fractionation mode* is then used in which the best possible selectivity is obtained by fine adjustment of pH and ionic strength.

The protein content is greatest in the starting step, although the ratio between total protein and product can vary greatly (1 : 1 to 100 : 1). If only a small proportion of product is present, conditions (pH, etc.) should be adjusted so that it can be preferentially adsorbed and selectively eluted. If the product and foreign substances are present in similar proportions, tests should be carried out to see whether adsorption of impurities rather than adsorption of product would be preferable. The product is then almost immediately available for the next step; the conductivity and pH remain unchanged, and the same buffer can be used in the second step (see Section Subsequent Steps).

Hydrophobic interaction chromatography provides a suitable introductory purification step if the crude product has a particularly high conductivity, e.g., after addition of more than 40 % ammonium sulfate for precipitation. The ammonium sulfate concentration should be chosen so that the product remains in the supernatant. The supernatant is then used directly as the sample for selective HIC adsorption and further purification of the product (e.g., [64]).

With a suitable combination of temperature and ionic strength, proteases can be separated selectively from other proteins and peptides if a hydrophobic matrix is used as the adsorbent [65]. Because hydrophobic interaction chromatography can operate with very large volumes and amounts of protein, and concentration can be achieved, chemically stable HIC media offer a good alternative to ion exchange as the initial step.

3.3.2.3. *Subsequent Steps*

In the starting step, the crude product is concentrated, prepurified, or merely rebuffered and freed from low molecular mass impurities. This provides an intermediate product with properties that depend on the initial purification rather than on the raw material. Subsequent steps are thus governed by this factor. Figure 13 shows some logical purification sequences; see also Tables 4 and 14.

Figure 13. Logical sequences of chromatographic purification steps

* HIC = hydrophobic interaction chromatography.

The choice is simplest if purification starts with desalting by gel filtration. In this case, 20 – 25 % of the column volume is applied as a sample. The intermediate product is diluted by a factor of ca. 1.4 so that a subsequent concentration step is required. Because ionic strength or pH can be adjusted as desired with the aid of gel filtration, the correct starting conditions for the next step can be obtained automatically, as in the purification of monoclonal antibodies shown in Figure 14 [46].

Figure 14. Purification of monoclonal antibodies from serum in three steps

Hatching denotes fractions containing monoclonal antibodies.

A) Desalting with Sephadex G-25: buffer 20 mmol/L sodium citrate, pH 5.3

B) Ion exchange with S Sepharose Fast Flow; bed height: 3 cm; linear flow rate: 300 cm/h (loading and washing), 5 – 10 cm/h (elution)

Buffers: a) 20 mmol/L sodium citrate, pH 5.3; b) 20 mmol/L sodium citrate, 140 mmol/L NaCl, pH 5; c) 100 mmol/L NaOH

C) Gel filtration with Sephacryl S-200 HR; bed height: 100 cm; linear flow rate: 7.5 cm/h; buffer 50 mmol/L Tris – HCl, 150 mmol NaCl, pH 7.5

If the total sample volume is greatly reduced in the first step by ion exchange in the concentration mode, the second ion-exchange step should be used for fine purification. In some cases, the same exchanger is suitable; its pH must then be modified to give greater selectivity. A small change in ionic strength determines adsorption and elution of the product. Because the concentrated intermediate product has a high ionic strength, it can also be purified by HIC: if necessary, the salt concentration can be increased even further.

If the crude product is relatively concentrated and good purification is obtained by ion exchange in the selective fractionation mode, a highly enriched product can be obtained in the second step. In the case of human interleukin 1 (IL-1), for example, anion and cation exchangers can be used consecutively [66]. The culture supernatant is first purified on a strong cation exchanger which binds IL-1. Elution is achieved by using the buffer needed for the second step. The intermediate product can be applied directly to a DEAE exchanger, and IL-1 is again bound. Elution is carried out selectively by increasing the ionic strength.

In all the above examples, a highly selective affinity chromatography step can also be included, generally after dilution to reduce ionic strength. If proteases, lipids, and other interfering constituents have already been removed, hardly any restrictions are imposed by the lability of the affinity medium. Two consecutive affinity steps often give a homogeneous end product. This route has been selected for the purification of tissue plasminogen activator (tPA) [60].

In the case of therapeutic agents, product oligomers or polymers often have to be separated. This is achieved by using gel filtration in the fractionation mode. In all cases in which particle size is an indispensable separation criterion, gel filtration should come at the end of purification, after all foreign substances have been removed. A buffer in which the product can be brought to its marketable form (formulation) should be used for this purpose.

[Top of Page]

4. Optimization

After individual methods and gel materials have been screened and a logical sequence of purification steps has been developed, the process should be optimized.

4.1. Purpose of Optimization

The product should be prepared as simply and economically as possible in a specific amount dictated by the market volume.

Costs must be optimized to ensure the economical utilization of chromatography in commercial use. In analytical chromatography, this is done by increasing the number of analyses per unit time and reducing the amount of sample required. The trend in this field is toward more efficient column materials with small particle sizes that give the maximum number of peaks, i.e., maximum resolution.

In contrast, the main purpose of optimization in preparative chromatography is to increase the productivity of each step, i.e., to optimize the amount of product obtained per unit time with the desired purity and biological activity. This is achieved by increasing the amount of product processed per run (throughput) and by increasing the proportion of product recovered (yield). Throughput is increased by optimizing both sample loading and linear flow rate, i.e., dynamic capacity in the case of adsorptive techniques. To increase yield, buffer solutions must be optimized because their composition and pH affect stability. Gel materials without adverse side effects (e.g., nonspecific adsorption) must be selected. Care should be taken to achieve early elimination of proteases that may affect product stability. Yields are also improved by shortening storage time, i.e., processing as fast as possible. Thus, using the correct dimensions in each step (see Chap. Scaling Up) and minimizing the number of steps by maintaining a logical sequence (Section Logical Sequence of Chromatographic Steps) are vitally important.

In contrast to analytical chromatography, the aim of preparative chromatography is not to resolve the sample into as many peaks as possible, but to exploit the selectivity of a chromatographic medium to separate groups of substances. A preparative chromatogram often shows only two or three distinguishable peaks. As illustrated in Figure 15, one or two peaks containing as much foreign material as possible are separated from a single product peak. Only in difficult separation problems requiring a high final degree of purity is the resolution of single substances desired as is the case in analysis. However, production of several substances from the same run may be required.

Figure 15. Preparative chromatograms for adsorptive techniques (A, B) and gel filtration (C)

These considerations accelerate processing and simplify the management (i.e., automation) and design of a production plant.

4.2. Optimization Parameters

Despite extensive investigation of aspects of chromatography such as thermodynamics, mass transfer, and kinetics, the chromatography of proteins remains largely empirical and is based on the experience of the user. This is mainly due to the complex properties of macromolecules and their interactions with chromatography media.

In addition, simple theoretical adsorption – desorption models cannot be employed in process-scale chromatography because permanent overloading occurs [52]. Nevertheless, certain parameters (resolution and throughput) can be used to give a theoretical description of optimization and to deduce a practical approach. Some of these factors are summarized in Table 17.

Table 17. Dependence of achievable resolution and throughput on various parameters (adapted from [67])

Parameter	Resolution	Throughput
Column length, *L*	$\sim \sqrt{L}$ under isocratic conditions (i.e., constant composition of elution buffer as in gel filtration)	~1/L
Column radius, *r*	depends on design (i.e., sample distribution at top of column)	$\sim r^2$
Temperature, *T*	higher temperature mass transfer favors	~*T*
Viscosity, η	mass transfer lower viscosity favors	~1/ η
Sample volume, *V*	has an optimum under isocratic conditions (e.g., gel filtration)	~ *V*
Flow rate, *J*	has an optimum, limited by the rate of achieving equilibrium (molecular size) and peak tailing	~ *J*

4.2.1. *Resolution*

The resolution (R_s) describes how well two substances can be separated from each other. In a chromatogram, resolution is defined as the distance between two peak maxima, i.e., retention volumes V_{e2} and V_{e1}, divided by the mean of the peak widths W_1 and W_2 at the base line (Fig. 16):

$$R_s = \frac{V_{e1} - V_{e2}}{1/2(W_1 + W_2)}$$

Figure 16. Symbols used in the definition of resolution R_s

The numerator is a function of selectivity, which depends on the separation chemistry. The denominator is a function of column efficiency, which depends on the particle size of the gel.

In the threshold region for overloading, the capacity of the gel bed also becomes significant:

$$R_s = \frac{1}{4}\sqrt{N}\frac{(\alpha-1)}{\alpha} \cdot \frac{k'}{(k'+1)}$$

where α is the selectivity and *N* is the number of theoretical plates (efficiency). The parameter *k′* is the capacity factor

$$k' = (V_e - V_0)/V_0$$

where V_e is the elution volume and V_0 the void volume.

In a purification scheme, each step has minimal resolution. Better resolution can increase the yield if fractionation is improved and less (contaminated) product has to be discarded.

In practice, the purification factor (i.e., the increase in the ratio of product to total protein obtained in a given step) is used,

rather than resolution, as a control parameter for optimization.

Selectivity describes how well a method distinguishes between two different substances. In preparative chromatography, increased resolution is achieved primarily by increasing the selectivity (Fig. 10); this can be recognized in chromatograms by a greater distance between peaks, i.e., $V_{e2} - V_{e1}$ in Figure 16. The selectivity of a given gel is usually controlled by optimizing both the starting conditions (e.g., pH and conductivity) and the elution conditions (e.g., gradient shape). However, in gel filtration, selectivity is dictated by the choice of gel.

Several substances compete for the binding sites on the adsorbent in less specific adsorption methods; therefore, capacity also increases with increasing selectivity.

Efficiency (*N*, number of theoretical plates) plays a minor role in optimizing resolution in preparative chromatography. It describes how effectively the equilibrium necessary for separation is achieved on the column. The number of theoretical plates and the height equivalent to a theoretical plate (HETP) are defined in Figure 17.

Figure 17. Calculation of the height equivalent of a theoretical plate (HETP)

Symbols: L = column length, cm; N = number of theoretical plates; V_e = elution volume, L; W = peak width, L

Efficiency is determined mainly by the particle diameter of the gel. Above a given level of efficiency, relatively little increase is obtained in the productivity of a purification step (see Section The Starting Step and Fig. 10). However, high efficiency is essential for achieving the required resolution in many complex separation problems [68].

The variable quality of gel bed packing can have a marked effect on efficiency; therefore, optimized packing instructions must be followed in preparative chromatography, and packing quality must be checked regularly. The number of theoretical plates *N* and, thus, the separation efficiency increase linearly with the square root of the column length. Therefore, with techniques such as gel filtration in which the composition of the elution buffer remains constant (i.e., isocratic techniques), resolution can be improved by using a longer column. In practice, however, column length is limited by band spreading caused by diffusion.

Capacity. The required resolution limits the available capacity since increased loading leads to peak broadening. This is especially apparent in isocratic methods, where the sample volume rarely exceeds 10 % of the column volume. In practice, therefore, a high resolution can be used to optimize capacity.

Flow Rate. Full use of the separative performance of a column with given selectivity, efficiency, and capacity can only be made if the maximal flow rate for the diffusion-dependent equilibrium is not exceeded. This optimal flow rate depends on the size of the molecules being separated, as well as on the particle size: the smaller they are, the greater is the permissible flow rate. Peak broadening due to tailing is observed if the maximum is exceeded.

4.2.2. *Throughput*

Optimization of throughput is a highly complex procedure which starts with methodical screening and gel selection. The final conditions chosen depend on economic calculations. For example, certain losses in yield may have to be tolerated to obtain higher throughput, or resolution may be improved at the expense of lower throughput to obtain the marketing advantage of a purer product.

The most effective way of increasing throughput is to increase column radius (throughput is proportional to the square of the radius, Table 17). This is the path taken in scaling up (Chap. Scaling Up). The throughput of a given column cross section is optimized by modifying the dynamic capacity and linear flow rate. Dynamic capacity denotes the possible loading under process conditions; it depends to a large extent on a linear flow rate, but also on properties of the chromatographic medium (ligand concentration on the matrix, porosity, particle diameter, and particle-size distribution) and on the compositions of the sample and the solvent. The sample composition is fixed, but the gel material, selectivity (governed by the conditions set up in the solvent), and flow rate are variables.

The gel material selected during screening (Section Screening of Chromatographic Methods (Method Scouting)) should provide the greatest throughput, i.e., the best combination of loading and flow rate. Among ion exchangers, for example, gel selectivity differs considerably (Fig. 18); throughput can thus be optimized by correct choice of the gel. After the gel has been selected, all the conditions that significantly affect capacity (pH, ionic strength, etc.) are then finely adjusted during the optimization process. Optimal operating conditions for one gel may give a lower dynamic capacity when applied to another medium. However, by modifying these conditions, the apparently poorer material may well yield significantly better results. A series of experiments to optimize dynamic capacity must be carried out on each basically suitable material (Section Selection Criteria). Agarose adsorbents have clear advantages in this respect (curve a, Fig. 19).

Figure 18. Selectivity of chromatographic ion-exchange media for the separation of transferrin (left-hand peak) and albumin (right-hand peak) at the same flow rate

A) DEAE ion-exchanger beads, diameter 60 µm; B) DEAE Sepharose Fast Flow, particle diameter 100 µm; C) Q Sepharose Fast Flow, particle diameter 100 µm; D) Mono Q, particle diameter 10 µm

Figure 19. Dynamic capacities of DEAE anion exchangers

Results observed are due to the combined effect of matrix properties and charge density. (published with permission [69])

a) DEAE Sepharose CL-6B (highly cross-linked agarose); b) DEAE Trisacryl M (hydrophilic acrylic polymer); c) DEAE Fractogel 650 (M) (hydrophilic vinyl polymer)

In practice, the mode of operation of the purification step (e.g., concentration or fractionation) may have to be established first (i.e., is water the main contaminant?). This indicates an appropriate flow rate range (Table 18). The dynamic capacity of ion exchangers and affinity media is determined within this range on small laboratory columns by using various flow rates. In the method of CHASE and ARNOLD, a sample solution is applied continuously to the column [55], [56]. After some time, increased product concentration at the column outlet shows that the component of interest is no longer being bound (Fig. 20). The slope of the curve indicates the efficacy of adsorption; its position (elution volume) is a measure of the binding capacity under the given conditions (pH, ionic strength, etc.). Both slope and position depend greatly on flow rate (Fig. 21).

Table 18. Typical flow rates for chromatography

Chromatographic technique	Mode	Linear flow rate, cm/h
Adsorption (ion exchange,	concentration	100 – 300 *
affinity, hydrophobic interaction)	fractionation	10 – 75
Gel filtration	desalting	100 – 200
	fractionation	3 – 50

* These values are also valid for all cleaning and regeneration procedures.

Figure 20. Calculation of dynamic capacity according to the Chase method (published with permission [55])

Low dynamic capacity results in a shallow breakthrough curve (A), high dynamic capacity gives a sharper curve (B). The ratio of protein concentration in the column outlet (c) to that in the column inlet (c_0) is plotted against the amount of protein applied ($c_0 \cdot f \cdot t$, where f = flow rate and t = time). Hatched areas represents the amount of protein bound if loading terminates when c/c_0= 0.1.

Figure 21. Dependence of the breakthrough profile on the flow rate (published courtesy of H. A. CHASE)

Flow rate, cm/h: a) 30; b) 60; c) 120; d) 240

Symbols: c = concentration of product in column outlet; c_0= concentration of product in column inlet

The objective of the purification step also determines the required selectivity, which affects not only resolution but also dynamic capacity. For a given gel material, the composition of the eluent should be determined before the dynamic capacity is examined to reduce the number of experiments required. With ion exchangers, for example, the best pH can be determined with a simple batch experiment [70].

4.3. Optimization of Ion-Exchange Chromatography

Sample load, linear flow rate, and slope or volume of the elution gradient are the most important variables in the optimization of ion-exchange chromatography. The required resolution and the degree of purity of the (intermediate)

product are fixed parameters.

If a laboratory test with a relatively small sample has given more than adequate resolution, the load can be increased until the required resolution is still just reached. The individual substances are then eluted earlier at lower ionic strengths due to displacement processes. To increase the load further, the gradient volume must be increased. Resolution increases steadily with the volume of the elution gradient [71]. Of course, this approach can be continued only until the dynamic capacity of the column material is exhausted.

With high loading, (Fig. 22 B), resolution becomes much less dependent on flow rate than with analytical loading (Fig. 22 A). Flow rate is then limited only by the gel properties.

Figure 22. Optimization of ion-exchange chromatography: dependence of resolution on flow rate

A) Column loaded with 0.75 mg of protein per milliliter of gel; B) Column loaded with 12 mg of protein per milliliter of gel

Resolution was determined by using a chromatogram with three peaks: a) resolution of peaks 1 and 2; b) resolution of peaks 2 and 3. In a column with a higher load, the resolution of two substances is less dependent on flow rate.

However, because a higher flow rate increases the peak volume [71], the gradient volume must be increased further to maintain the required resolution. In the above example with a load of 0.75 mg, a flow rate of 200 cm/h requires 8.5 column volumes instead of the 5 column volumes needed with a flow rate of 100 cm/h.

Under process conditions with high loading levels, resolution should be optimized by increasing gradient volume rather than by reducing flow rate [61]. The best results are obtained by using maximal flow rate and adjusting gradient volumes to the required resolution.

4.4. Optimization of Affinity Chromatography

Selectivity, and thus both the resolution and the capacity of affinity chromatography, are determined largely by the correct choice of ligands coupled to the matrix. Optimization is therefore achieved during method screening. Because the best ligands are not always available commercially, optimization requires in-house synthesis of the medium. For economic reasons, the manufacture of material for production-scale work should be handed over to a gel manufacturer who has the equipment and experience to produce the material to specification. Optimization of the dynamic capacity of this type of material is basically similar to that described in Section Throughput.

4.5. Optimization of Hydrophobic Interaction Chromatography

As in ion-exchange chromatography, the most important variables for optimizing hydrophobic interaction chromatography are the loading conditions (especially ionic strength), the linear flow rate, and the volume of the gradient or elution step. The resolution can be improved initially by decreasing the flow rate (Fig. 23) and increasing the gradient volume (Fig. 24). Typical values for good resolution are a flow rate of 50 – 100 cm/h and a gradient of 10 column volumes. Column loading is then optimized by selecting the lowest possible ionic strength for sample application. The protein to be purified should still bind to the column, but as much of the foreign protein as possible should be eluted to increase the product-binding capacity of the column. This strategy is especially favorable for highly hydrophobic proteins that can be eluted from the column only at very low polarities.

Figure 23. Optimization of hydrophobic interaction chromatography: dependence of resolution on flow rate

Calculated resolution of three pairs of proteins: a) Lysozyme – chymotrypsinogen A; b) Ribonuclease – lysozyme; c) Myoglobin – ribonuclease

Chromatography medium: Phenyl Superose HR5/5; gradient volume: 15 mL/mL of gel; sample: 50 μl of standard protein mixture containing 1 mg/mL each of lysozyme, chymotrypsinogen A, and myoglobin, and 2 mg/mL of ribonuclease; gradient buffer A: 0.1 mol/L potassium phosphate, pH 7.0, and 1.7 mol/L ammonium sulfate; gradient buffer B: 0.1 mol/L potassium phosphate pH 7.0

Figure 24. Optimization of hydrophobic interaction chromatography: dependence of resolution on gradient volume

Calculated resolution of three pairs of proteins: a) Lysozyme – chymotrypsinogen A; b) Ribonuclease – lysozyme; c) Myoglobin – ribonuclease

Conditions are the same as in Figure 23 except that flow rate is 0.5 mL/min.

Ammonium sulfate is commonly employed to adjust the ionic strength in hydrophobic interaction chromatography, but in some cases the use of other salts provides another means of optimizing separation. The salting-out effect of a salt, and thus its effect on protein binding and elution, can be estimated from the Hofmeister series:

(Ions are listed in the order of increasing salting-out effect)

Anions: = PO_4^{3-}, SO_4^{2-}, CH_3COO^-, Cl^-, Br^-, NO_3^-, ClO_4^-, I^-, SCN^-

Cations: = NH_4^+, Rb^+, K^+, Na^+, Cs^+, Li^+, Mg^{2+}, Ca^{2+}, Ba^{2+}

Other parameters such as temperature and pH have different effects on the hydrophobic interaction of proteins with the gel matrix and can also be varied to improve resolution. Some proteins are eluted more readily if the temperature is decreased because this weakens hydrophobic interaction.

4.6. Optimization of Gel Filtration

The most important variables in gel filtration are the linear flow rate and the column length. The required resolution and the selectivity of the chosen gel are fixed. Although flow rate has no effect on selectivity, it does affect resolution via efficiency, i.e., plate height (Fig. 25). The effect of flow rate on separation is different for substances of differing molecular mass (Fig. 26). The slow mass transfer of macromolecules leads to peak broadening and poor resolution, which can be overcome to some degree by reducing the flow rate. The minimum value for linear flow rate is about 2 – 3 cm/h, but if molecular mass differences in the sample are large (e.g., in desalting), separation can be effective even with flow rates of 100 – 200 cm/h. In the example shown in Figure 27, α-chymotrypsinogen (peak c) should be separated if the minimum flow rate of 2 cm/h (Fig. 27 A) is increased 12-fold (Fig. 27 B). Further optimization can be achieved easily by increasing the load.

Figure 25. Optimization of gel filtration: dependence of plate height on flow rate

a) Dispersion due to incomplete mass transfer; b) Eddy diffusion effects; c) Axial diffusion effects; d) Resulting profile

Figure 26. Optimization of gel filtration: dependence of plate height on flow rate and influence of molecular mass

a) Medium-sized protein, $M_r \approx$ 70 000; b) Small protein, $M_r \approx$ 17 000; c) Amino acid, $M_r \approx$ 200

Figure 27. Gel filtration of a mixture of IgG (a), transferrin (b), and α-chymotrypsinogen (c) on Sephacryl S-200 Superfine at flow rates of 2 cm/h (A) and 25.5 cm/h (B)

Column diameter: 2.6 cm; bed height: 85 cm; eluent: 0.1 mol/L Tris – HCl buffer, pH 8.0, containing 0.5 mol/L NaCl

Throughput can be optimized further by increasing column length. Mechanically stable gel materials are required because in this strategy productivity can be increased even more by increasing the flow rate. Figure 28 shows how productivity can be increased by doubling the column length from 90 cm to 180 cm. In a 90-cm column, a resolution of ca. 1.3 is achieved at a flow rate of 10 cm/h. Doubling the column length allows twice the sample load. However, productivity remains constant provided that the flow rate is kept at 10 cm/h. (The separation on the 180-cm column takes twice as long.) An increase in linear flow rate to 40 cm/h restores the resolution to the originally desired value with a fourfold increase in productivity.

Figure 28. Flow rate and resolution in columns with a length of 90 cm (a) and 180 cm (b) (published by courtesy of J. BERGLÖF, Pharmacia)

To obtain a resolution of 1.3 in a 90-cm column (a), the flow rate may not exceed 10 cm/h. In the 180-cm column (b), the same resolution can be obtained with a flow rate of ca. 40 cm/h.

Alternatively, improved resolution (on a 180-cm column at 10 cm/h) may also be used to increase yield as a result of better fractionation.

If the mechanical stability of the separation medium limits the flow rate, the gel bed can be divided into segments to eliminate stresses due to high flow rates. Zone broadening caused by the additional column segments is partially offset by the improved packing quality of the shorter column segments.

[Top of Page]

5. Scaling Up

Scaling up denotes an increase in the volume handled in a production cycle. It applies not only to all stages of chromatographic purification but also to the fermentation and isolation stages. An essential feature of scaleup is the introduction of new, larger pieces of apparatus, whose effects on chromatographic separation must be analyzed and balanced out.

The first important factor in scaling up is the decision to invest large sums in chromatographic media and the plant for the product. Processing enters a new and critical economic phase. The correct dimensions of the full-scale plant (Section Dimensioning of a Purification Cycle) and its optimal operation are essential factors in process economics. The scaleup phase starts as soon as large amounts of product are required for test purposes, e.g., clinical trials. These amounts must be manufactured under conditions similar to those required later for full-scale production. This involves factors such as process hygiene and opens up a new dimension, namely quality assurance (see Chap. Quality Assurance).

Scaling up of chromatography is relatively simple: “only” the column diameter has to be increased, the sample load then increases proportionally. However, a number of “nonchromatographic” effects, (e.g., the introduction of new apparatus and changes in sample composition occurring when fermentation is scaled up) must be counterbalanced to ensure that the separation results achieved with the large-scale equipment are the same as those obtained with the laboratory unit [72]. Typical parameters for the preparation of mouse 2 a monoclonal antibodies in the laboratory, pilot plant, and production plant are compiled in Table 19.

Table 19. Scaling up and optimization of ion-exchange chromatography for mouse 2 a monoclonal antibodies on S Sepharose Fast Flow [a]

Parameter	Research laboratory	Pilot plant [c]	Production plant
Column volume, mL	1	16	1500
Bed height, cm	1.2	3.0	3.0
Linear flow rate, cm/h	300	300	300
Column loading, L	0.05	3.79	425
Scaleup factor [b]	1	75	8500
Elution volume, L	0.006	0.025	2.3
Yield, %	95	95	95
Efficiency, %	80 – 85	80 – 85	80 – 85
Process time, min	25	160	180

[a] Sample: culture supernatant desalted by gel filtration on Sephadex G-25.
[b] Calculated on the basis of column loading.
[c] Conditions from laboratory changed as a result of the optimization of capacity and concentration of eluted product. Note that a laboratory-scale column is still used.

5.1. Transfer Protocol

Scaling up is often carried out not by the development department but by the pilot-plant staff. All relevant processing instructions and parameters should be available in a *transfer protocol.* This ensures that the results achieved during research and development are obtained in practice without costly, time-consuming repeat studies or modification.

The process that is handed over must meet the requirements of a production process; this necessitates close communication between research and pilot-plant staff (see Table 12). The purification scheme must be complete before it is handed over to the pilot plant.

Fixed Parameters. The choice of gel is an especially important fixed parameter because a change of gel means extensive work to determine the precise separation conditions required. In some cases, all the important parameters such as dynamic capacity, flow rate, and pH would have to be redetermined. For economic reasons, this work should be carried out only on a laboratory scale. Therefore, the task of the development department is to determine, before scaling up, which media are suitable for all production stages and to hand only these materials over to the pilot plant. Only these media ensure that the other fixed parameters remain constant in practice. This strict rule for gel selection applies even if optimization of the process has not been finalized, e.g., when the precise linear flow rate still has to be established.

Scaling up in this sense, does not include cases in which separation conditions have been determined with a “high-performance” material and transition to a production medium with larger particle size is envisaged (cf. Section The Gel Bank). This transition is still part of the research and development work for gel selection. Media should be found which allow achievement or improvement of attainable throughput with simple apparatus and minimal expense (Table 19).

The height of the gel bed and the linear flow rate should also be kept constant. With adsorptive methods, the ratio of the mass of the sample to the mass of the adsorbent remains constant. In gel filtration, however, the ratio of sample zone height in the column to column length is kept constant.

Matters are simplified if the sample composition (ratio of individual constituents to total protein concentration) has been optimized for separation and does not have to be changed during scaleup. In practice, this means that definitive

optimization of a chromatographic purification scheme can be achieved only when the production conditions for cell culture or fermentation have been established. Changes in upstream processes may have a significant effect on sample composition and thus on chromatographic separation conditions [72]; they create further optimization work.

If process development under these ideal conditions is not possible, proceeding with optimization to the utmost limits of separative performance may be inadvisable. Variations in sample properties, which are common with biological materials, should be taken into account by a certain tolerance range in loading and resolution rather than by repeated optimization. Tolerance of this type is important for product reproducibility with different batches of raw material.

Variable Parameters. The major variable in scaling up is the *column cross section.* With a given bed height, column volume and thus load increase proportionally to cross section. In gradient elution, the gradient volumes must also be increased in proportion to column volume.

An increase in column cross section causes other changes. Figure 29 shows the effect of column diameter on the *linear flow rate* at a constant pressure drop through the gel bed. A significant decrease in flow rate (30 – 40 %) occurs on transition from laboratory columns 1 – 5 cm in diameter to pilot plant columns 10 – 25 cm in diameter. Flow rate decreases because the mechanical support of the gel bed by the column walls rapidly becomes insignificant as the column diameter increases. In practice, this means that during optimization, flow rate should not be increased to the threshold of pressure stability of the gel medium. However, modern Fast-Flow media allow such high flow rates even in large columns that the rate no longer has to be reduced during scaleup. The maximum possible linear flow rate for the gel is not used for real processing.

Figure 29. Dependence of attainable flow rate on column diameter at a constant pressure

a) 0.1 MPa; b) 0.2 MPa; c) 0.3 MPa

If mechanically less stable media are used (as in gel filtration), the optimal flow rate should be determined in segmented columns in the laboratory. Segmentation of the gel bed (e.g., in 15-cm segments) reduces the mechanical strain imposed on the “stacked” gel particles by the throughflow and allows high productivity even with media of low mechanical stability. This approach has been of value in the production of albumin and insulin [6]. Resolution hardly changes because the packing quality obtained in each segment is better than in a long column. A segmented arrangement also gives high productivity with materials of better mechanical stability such as Sephacryl S-200 HR (see Table 20).

Table 20. Linear flow rate and productivity in a segmented gel filtration column used for albumin production

Gel medium	Total bed height, * cm	Sample volume, % of total	Flow rate, cm/h	Cycle time, h	Productivity, g h^{-1} 1000 cm^{-2}
Sephacryl S-200 sf	90	8	15	6	72 **
Sephacryl S-200 HR	90	4	75	1.2	180 **

* Each segment has a bed height of 15 cm.
** With automation three separations can run directly after each other in one column volume.

Other variables in scaling up are the storage times of the intermediate products, and of the materials with which they come in contact. These factors influence the choice of apparatus and the dimensioning of the plant (see Section Practical Examples and Case Studies and Chap. Process-Scale Chromatography Plants). Therefore, the transfer protocol should also include information on possible product-stabilizing measures and the materials (e.g., types of steel) that may come in contact with the product.

Reliable tolerance limits for the preparation of buffers should also be established [73].

Zone Broadening. The large apparatus used in scaling up causes additional peak dilution in the sample distribution system at the top and bottom of the column, as well as in the tubing and measurement cells outside the column. This dilution or zone broadening leads to poorer, possibly intolerable resolution [74]. If laboratory results cannot be reproduced in the pilot plant, the quality of the gel bed packing should be checked first. Satisfactory results can be achieved with modern production columns. Thus, for example, an HETP value (efficiency) of 0.034 has been measured in a column of 100-cm diameter. This correlates well with the values of 0.039 and 0.033 found in smaller preparative columns (diameter 37 cm) and laboratory columns (diameter 5 cm) shown in Figure 30.

Figure 30. Zone spreading on columns with a diameter of 5 cm (· · · · ·) and 37 cm (–) packed with Sephacryl S-200 Superfine to a bed height of 15 cm (published with permission [74])

Sample volume: 2 % of total bed volume, v_t; flow rate: 10 cm/h

Peak broadening can be avoided by using suitably coordinated columns and equipment (measurement cells, etc.) in an optimal system configuration.

5.2. Practical Examples and Case Studies

Numerous examples prove that direct scaling up is possible. The production scale depends on the product use. The commonly used phrase “large-scale purification” thus includes amounts from a few grams to several kilograms of biological product per production run [75].

Figure 31 shows the results of a process development study for purifying a filtered superoxide dismutase homogenate. Economic process criteria (Tables 2 and 14) were taken into consideration, and the demands for high product purity were satisfied [58]. The purification scheme comprised three steps. The crude product was first desalted on a gel filtration column, small molecules that would affect the capacity of subsequent ion-exchange chromatography were removed simultaneously. A strong anionic exchanger, Q Sepharose Fast Flow, was used for concentration and further purification in the second step. The final fine purification by gel filtration on Sephacryl S-200 HR yielded the product in the required purity. Scaleup was achieved in a total of four steps up to a level at which 4 g of superoxide dismutase could be obtained each day.

Figure 31. Development of a three-step process for purifying superoxide dismutase (published courtesy of J. BERGHOF, Pharmacia)

A) Desalting on Sephadex G-25; flow rate: 180 cm/h; buffer: 10 mmol/L Tris – HCl, pH 7.5; sample: 3500 mL; column: 25.2×43 cm (diameter × bed height)

B) Anion exchange on Q Sepharose Fast Flow; sample: 3780 mL, 12 mg/mL gel; column: 11.3×5 cm (diameter × bed height)

a) Sample; b) 10 mmol/L Tris – HCl, pH 7.5, 125 mmol/L NaCl; c) 10 mmol/L Tris – HCl, pH 2.0, 125 mmol/L NaCl; d) 10 mmol/L Tris – HCl, pH 2.0, 0.5 mol/L NaCl; e) 0.5 mol/L NaOH; f) Flow rate: 300 cm/h; g) Flow rate: 30 cm/h

C) Gel filtration on Sephacryl S-200 HR; flow rate: 30 cm/h; sample: 320 mL; column: 11.3×77.5 cm (diameter × bed height)

A similar purification scheme was developed for an anti-tPA monoclonal antibody [46]. The sequence included a desalting step, cation-exchange chromatography, and gel filtration for final purification (Fig. 14). The antibody was obtained in 95 % purity, with a yield of 75 %; ca. 2.2 mg of product was obtained from 35 L of culture supernatant. Affinity chromatography on Protein A Sepharose is an alternative to the process shown in Figure 14. Available capacity data show that a 5-L column of Protein A Sepharose would produce 100 g of antibody per cycle (i.e., in 3 h) [76]. Figure 4) shows the laboratory-scale separation. A survey of possible purification strategies for monoclonal antibodies is given in [76].

Plasma proteins have been purified on a large scale since the early 1970s [7], and processes have meanwhile been optimized for modern gel media. Figure 3) shows an example of process development for the production of albumin, together with data required for scaling up and optimal dimensioning. In the anion-exchange step, 350 g of albumin can be processed per hour per 1000 cm^2 of column cross section. In a typical production column of 80-cm diameter and 15-cm bed height, about 2.6 kg of albumin is produced per 90-min cycle. A column of the same diameter with a bed height of only 5 cm, packed with the cation exchanger CM Sepharose Fast Flow, can produce about 1.3 kg of IgG per hour (Fig. 2).

Finally, all biotechnological products such as human growth hormone or tissue plasminogen activator are purified using at least one chromatographic step.

5.3. Dimensioning of a Purification Cycle

The instructions for production processes should be developed during scaleup in the pilot plant, when considerable amounts of material are produced for testing purposes. Column dimensions must be calculated so that the planned production volume can be processed within the time available.

Basic data for this calculation are the volume of a batch of crude or intermediate product, the time interval between two batches, column length, linear flow rate, capacity of the gel bed, and the cycle time required for complete separation. This time covers all work, including any gel bed regeneration or sterilization that may be necessary. The minimum column diameter required to process the given batch volume within the available time can be calculated easily [77]. Because columns are not available in all diameters, at least the next largest size above the minimum column volume must be chosen. The actual cycle volumes and number of cycles can then be derived from the column data determined in this way.

This calculation is a simple way of obtaining an approximate value for minimum investment. The assumption is made that the plant is automated and can operate virtually on a 24-h basis. If this is not the case, correction can be made, e.g, by the arbitrary stipulation of available time.

[Top of Page]

6. Process-Scale Chromatography Plants

Planning and constructing a plant for the industrial purification of biomolecules require expert knowledge and experience in both biological sciences (biochemistry, microbiology) and engineering (process engineering, measurement, and control). Whereas experience in the chromatography of biological macromolecules stems mainly from laboratories, engineering experience is derived almost exclusively from the production areas of classical microbiology (fermentation) or chemical technology [78]. Biochemists must learn to handle construction materials such as stainless steel, which they do not normally regard as a matter for scientific consideration. Conversely, engineers must become accustomed to the relative "smallness" of process-scale chromatography systems and adapt themselves to the hygienic operation of a plant with pipework of only $\frac{1}{4}$-inch (0.64-cm) diameter or less.

6.1. Basic Design Requirements

The requirements of the development laboratory, the pilot plant, and the production plant differ.

A number of chromatography units and systems are available for laboratory operation. Some are specially designed for the purification of biological macromolecules. Examples are the Fast Protein Liquid Chromatography and BioPilot (Fig. 11) systems in which the materials used (borosilicate glass, titanium, fluorinated plastics) and the specifications (flow rate, pressure range, gradient programming, reproducibility) are matched to the requirements of the separation principles and media suitable for protein separation [79], [80]. However, transfer of a laboratory purification process to the pilot plant produces additional requirements that are not always met by these systems (see Chap. Scaling Up).

Pilot Plant. In the pilot plant, apparatus for scaling up and preparing the product for testing purposes is required [80]. Units with a throughput of between 1 – 10 L/h and 400 – 500 L/h are used in pilot studies (smaller units can be used in a laboratory). They should be able to meet the demands of different chromatographic methods (e.g., isocratic or gradient elution, monitoring parameters such as pH and conductivity). A relatively large number of fractions must be obtainable if product fractionation has not been accurately defined. In production, the purification process is usually so well-defined that only two or three fractions are taken in a very reproducible manner.

The precise dimensions of the individual process steps and their automation should be developed in the pilot plant. During the experimental phase of automation, each modification and intervention must be readily achievable. However, because the work is carried out with relatively large amounts of valuable product, safety measures must be emphasized in the event of malfunction. Disturbing external effects (e.g., failure of the power supply) should be excluded, and the control unit should be separated spatially from areas in contact with the product. Good hygiene must also be observed where necessary. All results should be documented. For these reasons, the plant for the pilot phase must be highly flexible and easy to operate.

Production Plant . Because of the special properties of each biological product and the related production process, an individual solution is generally required for the production plant. The controlled, reproducible execution of each run (i.e., plant reliability) is extremely important. Flexibility becomes less important than in the pilot plant because intervention in the process is undesirable and should be necessary only for safety reasons. However, if only a few production batches are required per year, the production unit may be a multipurpose plant with built-in flexibility for different products.

Together, the development laboratory and pilot plant must define precisely the following process parameters:

- separation media and bed height
- productivity, g h^{-1} L^{-1} (column volumes)
- linear flow rate, cm/h
- counterpressure from gel bed
- buffer types, permissible tolerance range (pH, conductivity)
- stability of sample and buffer
- material in contact with solutions
- product sensitivity (shear forces)
- yield, detection procedure
- cleaning in place protocols
- lifetime of the separation media
- volumes (product and buffers)
- number of fractions
- process control parameters
- safety measures

The requirements for flexibility, process hygiene, and the production area (e.g., buildings) form another group of criteria which must be satisfied in plant design. The plant is generally a closed system from which contamination cannot reach the surroundings and into which outside impurities cannot penetrate. In pharmaceutical processes, the plant with its packed columns can be kept sterile and pyrogen-free by cleaning in place (CIP). Sterilization in place with steam (SIP) may also be required. For this, the gel material is removed from the column and sterilized separately. Sensors such as the UV measuring cell should also be removed from the unit before sterilization.

The suitability of the plant for a purification process must finally be demonstrated by validation (Chap. Quality Assurance).

6.2. Plant Design

Large expenditure of time and money is involved in planning and selecting the apparatus for a preparative chromatography plant. Conventional builders of chemical production plants do not generally have the relevant know-how. Effective cooperation of the pharmaceutical industry primarily with manufacturers of chromatography media who already have experience in general production (especially in the pharmaceutical sector) may be required to find optimal solutions.

A chromatographic production plant can be divided into seven functional modules whose equipment can be planned more or less independently of each other (Fig. 32).

1. The first *tank module* consists of tanks for storing the sample, the elution buffers, and the regeneration buffers, and for preparing buffer solutions.
2. The *delivery module* comprises tubing to the columns, valves controlling the choice of elution buffer, pumps delivering process fluids, and safety devices that protect columns from excess pressure and the penetration of particles or air.
3. The *control module* is essentially an automated unit that is suitably programmed for the process. It controls the valves, the adjustment and regulation of flow rate, and the response to signals from monitoring devices.
4. The *separation module* is the heart of the plant and contains the packed chromatography columns in which purification occurs. The column dimensions and the linear flow rate determine the design of the delivery module and the rest of the plant. The separation module also includes the connector tubes and valves which allow flow reversal or the hygienic isolation of columns when the plant is not in operation.
5. The *monitoring module* is connected to the columns with the shortest possible tubing. This module consists of devices that monitor the course of the process, usually via UV absorbance. The module may also contain flow-through cells for measuring conductivity and pH.
6. The product is isolated in the *fractionation module*, which contains valves and supply leads to the product tanks. In automated processes, the control module regulates fractionation by evaluating UV signals and switching valves accordingly.
7. The product is collected in the second *tank module.*

Control and documentation of the process are performed in a fully automatic control module (not shown).

6.2.1. *The Chromatography Column*

The column and the packed gel bed form the most important part of a chromatographic plant. Production columns made of stainless steel, glass, or plastic can be obtained in various designs, with adjustable adapters or fixed endpieces to isolate the gel bed. Diameters range from 5 to 180 cm and lengths from 5 to 100 cm. In long gel beds, problems may arise due to mechanical stress; segmented “stack” columns can then be used [74, pp. 87 – 89]. The choice is made according to process data regarding bed height, linear flow rate, and required productivity (diameter). The pressure gradient across the gel bed and the chemical specifications of the process determine the choice of construction material for the column. Glass possesses some advantage as a biocompatible, chemically resistant material. Visual inspection of packing quality, separation performance, and precipitated material on the gel bed is desired, as is possible in laboratory columns. However, only the separation of colored substances can be followed visually. Moreover, with columns more than 10 – 20 cm in diameter, only an insignificant portion of the gel bed can be inspected optically. In this case, the only effective controls of packing quality are the determination of the HETP value (Fig. 17) and the elution curve (UV absorbance). For safety reasons, especially when working at high pressure, a high-grade steel column is often preferred.

An adjustable adapter in the column head facilitates packing and allows correction if the bed volume changes. It also increases the flexibility of the column for use in different processes. The adapter should have a central device to allow adjustment and fixation for easy handling. In production columns, however, the use of fixed column ends is often more economical and hygienic. Less dead space is available in which microorganisms can accumulate. Columns can still be packed by relatively simple procedures without loss of convenience.

An essential factor in column operation is a description of the procedure for packing the gel bed with different chromatographic media; this should be issued as a set of instructions in the same way as for other plant equipment. The gel and column form an inseparable functional unit. Modern, mechanically stable media can be packed at very high flow rates in large columns just as well as in laboratory columns; they give fully analogous separation results provided the column is of optimal design (see Section Transfer Protocol). A larger, separate pump may be planned for packing. Not more than 80 % of the flow rate used for packing should be employed during the separation process.

6.2.2. *Process Monitoring*

After the columns, the devices used to monitor separation are the most important components of a chromatography plant. Sample components are generally detected in the column eluate by means of their *UV absorbance* (e.g., at 280 nm). In an automated system, these signals also control fractionation and guide the product into the correct tank. Malfunction of the UV monitor can be a very expensive disaster. Although the typical operating life of UV lamps is around 8000 h, in planning the plant continuous monitoring of the lamps should be considered [73].

The *linear flow rate* is also important for process control; it affects both resolution and productivity. The flow rate should,

therefore, be recorded continuously with flow-through cells. Units based on inductive or turbine principles are used most commonly. The signal supplied by the measurement converter can be used by a control unit to compare the actual flow rate with the programmed value. In case of deviation, the pumps can be adjusted. Deviations may, for example, arise when a sample component is deposited gradually on the gel bed or on an in-line filter. After the flow-through signal has been integrated to give the total flow volume, it can also be used to control process volumes. A fixed volume can be allocated to each process step: sample application, washing, or elution. These volume segments provide a basis for automation (Section Automation and Safety Devices). The fixed scheme can be overridden by signal-dependent steps, i.e., the valve switch can be controlled by monitor signals such as those provided by UV absorbance during fractionation.

Particularly in adsorption (ion-exchange or affinity) chromatography, *pH* and *ionic strength* are control parameters that govern reproducibility and the general success of separation. Regeneration of the gel bed can also be controlled. Both elution with a continuous gradient and fresh sample application after regeneration can be automated by evaluating the signals from flow-through pH or conductivity cells.

The required pH and ionic strength ranges in which measurements should be made must be defined. The fluids that come in contact with the cells must be known before a suitable item of equipment can be selected. To operate reproducibly, pH sensors in particular should be recalibrated before each run.

6.2.3. *Pumps and Valves*

Biological macromolecules are often sensitive to strong mechanical or thermal effects, which may arise in pumps and valves. The choice of a suitable pump is one of the least predictable tasks in plant design. Experience with the product determines the type of pump drive used. For example, gear pumps cause problems in the production of human albumin. Pumps suitable for process-scale chromatography include peristaltic pumps, double-membrane pumps, and some rotor pumps. In addition to product-specific restrictions, the required flow rate, pressure range, degree of suction, throughput, and viscosity of the pumped medium are the major selection criteria. Because of the chemical composition of the liquids, special materials must be selected for pump components such as ball valves, membranes, and seals.

In closed systems, the tanks are connected to the pumps and column outlets via valves. Solenoid or pneumatically controlled valves are generally used. Three-way valves have the advantage of reducing the total volume of the tubing system; this is particularly important in the fractionation module (see below). However, valves of this type are not available, which meet the hygienic demands of a pharmaceutical process. Butterfly valves with flaps or plug valves are used. Two-way valves, especially membrane valves, are preferable from a hygienic point of view. The disadvantage of a rather larger tubing volume is of little importance in the supply leads and can be offset by appropriate design measures. Apart from in-line filters and flow-through cells, valves create the greatest flow resistance in the plant and thus may need to be optimized [74].

Malfunction is highly undesirable in valves that direct the product into the appropriate tank during fractionation. Therefore, monitoring of the proper position of the valve and appropriate reaction of the control unit may be required in case of valve malfunction.

6.2.4. *Automation and Safety Devices*

Automation of the chromatographic process is particularly desirable when numerous cycles must be run in succession to achieve high productivity and plant utilization (Fig. 33). Because automation allows several process parameters to be monitored simultaneously, it increases reliability and reproducibility. The fact that variations in the quality of biological materials make human supervision indispensable does not contradict this. Electronic data processing affords numerous solutions for the automation of production processes, some of which differ greatly in relation to performance, user-friendliness, start-up time, and cost [81].

Figure 33. Increasing productivity through automation in the anion-exchange chromatography of plasma on DEAE Sepharose Fast Flow

Column diameter: 11.3 cm; bed height: 15 cm; flow rate: 200 mL/min at 20 kPa; sample: 2.9 L of desalted bovine plasma (87 g of protein per cycle)

Chromatographic separation is less troublesome to control than fermentation because relatively few parameters must be monitored. A proven concept for the automation of process chromatography thus uses control devices that have fixed, specially designed, built-in software and hardware. Programming of these units can be learned and mastered quickly even by laymen. Process data such as flow rate or volume breakpoints for process control (Section Process Monitoring) are simply entered into an existing program. Programming is user-friendly and is based on a menu driven dialogue procedure. The hardware of these “dedicated controllers” [81] can control a chromatographic plant with the aid of 10 – 20 programmable outputs for valve switching and for the power supply to peripheral apparatus. A pump can be regulated and signals from up to four monitors can be evaluated for control purposes. In addition, sensors can be included which, for example, give an alarm signal that switches off the process if the pressure rises, the pH exceeds a preset level, or a valve malfunctions. These alarms may also produce more flexible responses such as reduction of flow. Table 21 summarizes some points to be considered in process control and monitoring, including the necessity for an alarm signal.

Table 21. Crucial parameters in process control and monitoring of process-scale chromatography

Parameters	Precautions	Alarm function required

pH	continuous monitoring, defined limits	+
Conductivity	continuous monitoring, defined limits	+
Feedstock concentration	off-line analysis, defined limits	
Air presence in the column	continuous monitoring, in-line air trap	+
Tank levels	level sensors	+
Flow rate	continuous monitoring	+
Pressure	continuous monitoring	+
Column	operation within given specifications, in-line filter, feedstock preparation	
Product monitors	signal level control, off-line calibration	+
Pump	continuous monitoring of flow rate and pressure	+
Valves	continuous monitoring of position	+

Despite automation, provision must be made for manual operation for reasons of safety and economy if the control apparatus fails. Because all parameters of a production process need documenting as well as monitoring, the control unit should be able to store data or direct it to a superior computer located elsewhere. Documentation can be performed with a personal computer, suitable software is offered by equipment manufacturers.

6.3. Effects of Apparatus on Separation

Zone broadening before separation or remixing after successful separation reduces resolution. Such effects may occur in the tubing, at the column inlet and outlet, in the flow-through monitoring cells, and in the leads of the fractionation module; they must be minimized by appropriate design. Apparatus effects are discussed in detail in [74].

The use of narrow tubing in which turbulent flow predominates reduces the peak tailing caused by laminar flow in wide tubes. Uniform distribution of flow across the column cross section then becomes the critical factor in zone spreading. In practice, $\frac{1}{4}$-inch (0.64 cm) tubes are commonly used for throughputs up to 40 L/h, ½-inch (1.27 cm) tubes up to 400 L/h, and 1-inch (2.54 cm) tubes at greater throughput. Tubing may be made from plastic (e.g., polyethylene) or stainless steel.

The sample distributing system at the column head usually consists of the inlet tube and a fine net covering the gel. Here, the axial counterpressure opposing entry of the sample into the gel must be considerably greater than the radial pressure; a high radial pressure would prevent the sample from spreading over the column cross section. The pressure gradient across the mesh covering the gel surface must be uniform. Critical factors in zone spreading at the column inlet are depicted in Figure 34. The mixing chamber at the bottom of the column must be as small as possible to prevent remixing. For the same reason, the total volume of the tubing and measurement cells between the columns and fractionation unit must be minimized. Dead spaces from which contaminants can reach the purified product must be avoided, especially after the column.

Figure 34. Zone spreading at the column inlet (published with permission [74])

To minimize zone spreading, transport times to points a and b should be the same; pressures at a and b should also be the same so that equal flow rates are obtained at points c and d. The mixing chamber should be as small as possible to prevent eddying and back-mixing. The boundary width *w* should be small compared to the peak width caused by dispersion in the column.

Another cause of zone broadening may be pump pulsation, which can largely be eliminated by a pulsation-dampening device such as a bubble trap. Optimal results can then be achieved even with pumps that exhibit relatively marked pulsation (e.g., double-membrane pumps).

[Top of Page]

7. Quality Assurance

Chromatography is an effective purification method for routine production of a number of hormones and therapeutic enzymes from both conventional and genetic engineering sources [7], [75]. The quality assurance of these products is one of the most important tasks to be met before drugs produced by modern biotechnology are generally accepted. Some of the aspects relevant to process-scale chromatography are summarized in Figure 35.

Figure 35. Factors involved in assuring end-product quality

Quality assurance is achieved by the purification process itself (i.e., by working under aseptic conditions), by appropriate design of the production plant, and by the properties of the chromatographic media. Together, these features should ensure reproducible operation. Furthermore, tests of biochemical and biological purity are carried out on the product.

Good Manufacturing Practice. Like other process steps, process-scale chromatography must comply with the extensive safety requirements of organizations such as the Food and Drug Administration (FDA) in the United States. Development and production must constantly be adapted to conform to new regulations, such as those specified in “current Good Manufacturing Practice” (cGMP) and other official recommendations [49], [82-90]. Good manufacturing practice means that documentary evidence is kept to ensure reliable, safe operation. Quality standards are defined and converted into measurable parameters. Records must be kept to show that standards are being upheld. Despite the expense and effort involved, the production process must remain economical.

Regulations for GMP are flexible when new, generally applicable results may lead to the adoption of novel procedures and when special product properties must be considered. End-product control and in-process control of critical steps in production are required. A great deal of attention is paid to processing aids, e.g., components of the culture medium in cell culture or the gel medium in chromatography. Their specifications, processing behavior, and suitability must be documented if possible with the help of the supplier. However, the user (i.e., the producer) bears ultimate responsibility. The use of substances with intrinsic biological activity, toxicity, or pyrogenicity should be avoided.

In process-scale chromatography, the purification process must be described in detail. Reproducibility with respect to the removal of special contaminants (e.g., pyrogens) or the composition and activity of the end product must be demonstrated by appropriate analytical methods. The chromatographic medium must not release harmful contaminants into the product. If foreign substances can be tolerated in the end product, their maximum limits should be defined and their levels monitored. With DNA and viruses, purification factors for the entire process and for its individual steps should be given.

Chromatography is performed aseptically. The process description must, therefore, include CIP measures which ensure that contaminants can be removed and that a predefined standard of hygiene is maintained. Hygiene in process-scale chromatography starts with careful, regular maintenance of the gel materials. The methods employed depend on the nature of the sample responsible for contamination. The use of sodium hydroxide solution is the method of choice not only for gel maintenance but also for the inactivation of viruses, microorganisms, and pyrogens. The solution sterilizes the system and washes out contaminants.

Suitability of the Chromatographic Plant. After specifying all the necessary requirements, the chromatographic purification plant is planned, built, and finally installed. The first phase of suitability testing begins with the commissioning of the plant, which is carried out by the user together with the manufacturer. Criteria for testing the equipment, the calibration of inbuilt instruments, and suitability must be established. Suitability tests may, for example, include the introduction of malfunctions and testing the emergency stop function. When this hardware-oriented testing phase is complete, validation of the entire process starts, i.e., “the systematic testing of the essential operating steps and equipment in development and production, including the control of pharmaceutical products, with the aim of ensuring that the product can be manufactured reliably and reproducibly in the required quality when the stipulated production and control processes are applied” [91]. Documentation is required to prove that the equipment is designed to maintain a predetermined level of process hygiene and allow the process to function reproducibly at a predetermined level. Challenge tests (i.e., setting the processing pH to the limiting value defined for reproducible separation) and “worst case” assumptions are made during validation.

Suitability of the Chromatographic Media. Media for process-scale chromatography are one of the most critical components in a purification process; they must function reproducibly in the plant and be compatible with CIP measures. Validation of their suitability must always be undertaken with regard to the system as a whole.

Like plant evaluation, characterization of the medium (i.e., the determination of process-relevant specifications) is very important. The integrity of the gel matrix should be tested in the presence of typical chemicals used for cleaning and sterilization.

A test program for the Pharmacia ion-exchange media based on the Sepharose Fast Flow matrix follows:

1. Autoclave five times for 30 min at 121 °C and pH 7.0
2. Maintain at 40 °C for one week in
   - Phosphate buffer, pH 7.0, 50 mmol/L
   - Acetic acid, 1 mol/L
   - Sodium hydroxide, 1 mol/L
   - Urea, 8 mol/L
   - Guanidine hydrochloride, 8 mol/L
   - Ethanol, 24 vol %

After treatment, all media must pass quality control and function tests.

Studies of this type should already have been carried out by the gel manufacturer. Deterioration of separative performance should not occur even after prolonged exposure (at least one week) to the test substances. This can be expressed in weeks of constant exposure or in number of cleaning cycles (see Fig. 9).

A small-scale separation should be performed under the original processing conditions before a new batch of separation medium is used in production. This step has to be taken by the user of the media.

Sterile and Aseptic Operation. For genetic engineering products, the raw material is often of microbial origin and the

product possesses very limited stability under sterilizing conditions. Therefore, the process is often aseptic rather than fully sterile. However, measures must be available to allow regular sterilization of the plant and ensure a sterile end product. Relevant FDA requirements are given in [83].

Good process hygiene not only reduces the risk of product contamination but also improves the economic efficiency of the process, for example by increasing the lifetime of gel media. Separation media employed in plasma fractionation have been in use for as long as five years. With immunoadsorbents, 200 production cycles have been achieved [92]; modern, rigid ion exchangers have undergone as many as 600 cycles in the purification of albumin [61].

Good process hygiene is achieved by the use of pyrogen-free water of the same quality as “water for injection purposes” (United States Pharmacopeia, USP XX), which can be obtained by distillation or reverse osmosis. All buffer and cleaning solutions and, if possible, the sample should be sterile-filtered (filter pore diameter 0.22 µm). The production room should have a clean air supply, and personnel must wear clean protective clothing and caps. The columns and tubing system should be rinsed from time to time when the plant is not in use. Slow flow rates can be used, and the volume of rinsing liquid required can be reduced by recycling and filtration. Columns should be flushed with a cleaning solution (e.g., 1 mol/L sodium chloride, 0.1 mol/L sodium hydroxide) at regular intervals during prolonged downtimes [93].

Maintenance of Gel Materials. Process hygiene in chromatography starts with thorough, regular care of the gel materials by methods that depend on the nature of the contaminants. In general, the frequency of cleaning increases the “closer” the purification step in question is to the crude material. The properties of various crude materials give important hints for planning a maintenance protocol [94].

Plant extracts normally contain little lipid material but large amounts of charged polyphenols with varying molecular mass as well as colored hydrophobic substances. Polyphenols can cause decomposition processes to occur on the surface of anion exchangers where they accumulate. Samples of animal origin, including plasma, are rich in lipids which may bind to proteins. The proteins and lipids may be adsorbed on the matrix surface and can, in turn, bind hydrophobic proteins. This effect is sometimes observed as a gray zone in the gel bed and leads to an increase in column counterpressure. Secretory microbial systems yield a sample containing few lipids and proteins, but they can still cause problems if an antifoaming agent has been added to the culture medium. Nonsecretory microbial systems furnish a crude, lipid-rich product after the breakdown of cell membranes. In mammalian cell expression systems, the product is usually secreted into the medium. Because of the relatively low concentration of product, the components of the culture medium constitute the major impurities in cell cultures. Cultures of animal cells cause relatively few problems due to decomposition or other effects in chromatography columns.

Individual chromatographic procedures have different resistances to the stresses described above. The maintenance protocol shown in Table 22 generally removes both lipids and proteins from the gel to a satisfactory degree. Ion exchangers are frequently used as the first step in a purification procedure. The most serious problem in this situation is caused by the binding of phospholipids to charged groups; anion exchangers are most affected because the phospholipids are generally negatively charged. The bound lipids in turn bind neutral fats and hydrophobic proteins.

Table 22. Basic protocol for cleaning in place (CIP) of chromatography columns

Step	Aim	Washing solution *	Column volumes used
1	removal of proteins bound by strong ionic bonds	filtered sodium chloride, 2 mol/L	0.5
2	removal of proteins or lipids bound by strong hydrophobic bonds	sodium hydroxide, 1 mol/L	4
3	removal of precipitated protein	acetic acid, 75 vol %	2
4	removal of lipids and highly hydrophobic proteins	ethanol, 40 vol %	10

* Column is washed with water or buffer between steps. Flow rate is ca. 50 cm/h but depends on the gel matrix.

Among hydrophobic separation media, phenyl and butyl gels with their relatively low hydrophobicity present few maintenance problems. Octyl Sepharose and similar gels are more difficult to clean. Temperature reduction may help by reducing binding forces by 20 – 30 %. Because gel filtration concludes the purification scheme, samples are normally very clean and cause no problems. In general, a small amount of precipitated protein can be removed with 1 – 2 mol/L sodium chloride solutions. Lipids can generally be removed by combining temperature elevation to 40 – 60 °C with other measures such as rinsing with sodium hydroxide solution.

Sterilization and Removal of Pyrogens. The fear of contamination of biological products derived from plasma or mammalian cell cultures is considerable because these sources may be infected, for example, with hepatitis or AIDS (acquired immune deficiency syndrome) viruses.

Fortunately, nucleic acids and other hazardous contaminants such as lipopolysaccharides bind very effectively to anion exchangers [95], [96]. Thus, they can be removed by an early ion-exchange step. Effective decontamination methods for inactivating adsorbed contaminants are an essential prerequisite in the manufacture of modern biotechnical products for therapeutic use. Autoclaving, a bacteriostatic agent, or sodium hydroxide is generally used; their advantages and disadvantages are listed in Table 23. Sodium hydroxide is the best agent for inactivating viruses, bacteria, and their products (spores and endotoxins) in chromatography [97]. For example, HTLV is inactivated by 0.1 mol/L sodium

hydroxide within 10 min at room temperature [98]. The entire chromatographic system can be sterilized and cleaned simultaneously with sodium hydroxide solution. Pyrogens are degraded and flushed out. Unlike bacteriostatics, for example, no risk of product contamination exists.

Table 23. Advantages (+) and disadvantages (–) of decontamination methods for inactivating adsorbed contaminants

Autoclaving	Bacteriostatics	Sodium hydroxide solution
+ gives sterility	+ result in a low bacterial level (high sterility)	+ sterilizes complete column
– has no cleaning effect	– only possible with certain affinity media	systems
– does not destroy endotoxins	– do not remove endotoxins	+ has good cleaning effect
– is not possible with packed	– have no cleaning effect	+ destroys pyrogens
columns	– lead to risk of contaminating traces in the	+ cannot contaminate the
	product	product
		– requires careful handling

The action of sodium hydroxide depends on its concentration and temperature. Results for *Pseudomonas aeruginosa* cells and *Bacillus subtilis* spores are shown in Table 24. Other microorganisms tested include *Staphylococcus aureus, Escherichia coli*, the yeast *Candida albicans*, and the fungus *Aspergillus niger* [61]. These studies concluded that 0.1 mol/L sodium hydroxide is an effective disinfectant for bacteria and yeast; a concentration of only 0.01 mol/L is required for gram-negative bacteria. However, 0.5 – 1 mol/L alkali is required to reliably kill fungi [61]. Endotoxins can also be degraded by sodium hydroxide in a relatively short time (Fig. 36).

Table 24. Concentration and time required for sodium hydroxide to inactivate microorganisms

Microorganism	NaOH concentration, mol/L	Temperature, °C	Time, h
Pseudomonas	0.15	ca. 20	16
aeruginosa[*]	0.25	ca. 20	16
	0.5	ca. 20	5
	1.0	ca. 20	4
Bacillus subtilis	0.5	4	76
spores [99]	0.5	20	8
	1.0	4	22
	1.0	20	2

[*] Data courtesy of F. HASKO, Institute of Haematology, Budapest, Hungary.

Figure 36. Inactivation of *Escherichia coli* endotoxin by sodium hydroxide at room temperature

Sodium hydroxide concentration, mol/L: a) 0.1; b) 0.5; c) 1.0

The above discussion shows that the selection of separation media which can withstand relatively high concentrations of sodium hydroxide is important. However, affinity media are an exception because the appropriate CIP procedure is dictated by their ligands. Alternative cleaning methods involve killing bacteria with 70 vol % ethanol and solubilizing pyrogens with 4 mol/L urea. Formaldehyde or phenol has also been used to clean immunoadsorbents without loss of activity of the separation medium.

[Top of Page]

8. Developments

Process chromatography is a relatively young branch of biotechnology. Significant developments can, therefore, be expected.

One particularly weak point of all currently available chromatographic methods in the initial purification step is the need to free the crude product from particulate components. The isolation steps used for this (⟶ Biochemical Separations – Product Isolation) are in some cases difficult to operate on a large scale (e.g., centrifugation with its risk of aerosol formation) or otherwise unsuitable for simple, direct scaling up (e.g., many membrane techniques). In addition, this step is time-consuming and decreases the yield of product.

A “chromatographic link” between cell cultures and final purification is obtained by using adsorbents (ion exchange) with very large particle diameters (>150 µm) that are based on highly cross-linked agarose. They allow isolation and concentration of products at very high flow rates (13 – 18 m/h) even with only partially filtered crude product solutions. Conventional chromatographic equipment can be used; columns do not become blocked; and the gel bed can be regenerated relatively easily because of the high chemical stability of matrices such as cross-linked agarose.

The technology of gel manufacture is advancing. Tailor-made separation media will be available for specific applications, e.g., special affinity media, ion exchangers with a high capacity for small molecules, and gel filtration media with special separation ranges suitable for monoclonal antibodies or recombinant DNA products.

The chemical – mechanical stabilities and capacities of many affinity media will be increased by the use of highly cross-linked matrices.

The oldest, dextran-based gel filtration media still have the highest selectivity but relatively poor mechanical and chemical stability. Attempts to produce highly cross-linked macroporous matrices for gel filtration have only improved stability; therefore, a compromise must be made between selectivity and adsorption behavior. A new generation of gel filtration media based on agarose – dextran mixed polymers combines the stability required for process media with the very high selectivity of the old materials.

In contrast with the trend toward tailor-made separation media for specific processes, an alternative approach modifies individual products for a standardized purification scheme; the aim is to use a single, highly specific affinity material to purify many products. This is conceivable on the basis of work with fusion proteins. A gene coding for the desired product is fused with the gene for a fragment of protein A and expression yields a fusion protein with a protein A marker that can bind to IgG Sepharose Fast Flow. This affinity medium would be suitable for all products fused with protein A [100], [101]. However, a number of problems (e.g., subsequent cleavage of the marker in each case) must still be solved.

1. Introduction

The separation and purification of fermentation products can be the major economic factor in commercializing a biochemical process. Although few rigorously documented studies exist, numerous unpublished reports suggest that separation can account for 75 % of the total cost of the process. This is particularly true when the product is a protein, enzyme, or antibody.

The major reason for the high cost of purifying fermentation products is the nature of both the processes and products involved. Many products, especially proteins, are fragile molecules. Products required for clinical purposes must be ultrapure. The products of fermentation processes are formed in a very dilute aqueous solution, which contains solids (cells or cell fragments) that must be removed. The need for solids removal, product concentration, and subsequent purification yields bioseparation schemes consisting of numerous processing steps.

In general, a bioseparation sequence is composed of four main classes of separation steps [1], [8]:

1) Removal of insolubles (i.e., cells and cell fragments)
2) Product isolation (product is concentrated; process volume is decreased)
3) Product purification (a specific, high-purity product is obtained)
4) Polishing (the product is made acceptable for the consumer)

Table 1 shows quantitative product information for these four general steps for antibiotics.

Fermentation products include low molecular mass organic molecules (e.g., acetone, acetic acid, and ethanol), amino acids, antibiotics, proteins, antibodies, enzymes, lipids, hormones, polysaccharides, and vitamins and are summarized in → Biotechnology, Chap. 3.6. Many of these substances are described in detail under separate keywords. Proteins, enzymes, antibodies, and some hormones are fragile molecules; most of the other products are robust. Enzymes and antibodies require a specific three-dimensional structure for their biological activity. This structure can be irreversibly altered (denaturation) by extremes in pH, temperature, and shear or by exposure to air – water interfaces or nonpolar solvents. However, most of the other molecules listed above are not damaged by extreme conditions; thus their purification is somewhat simpler.

Categorizing the scale of bioprocesses is somewhat imprecise. A method has been described that is based on the type of product and the capacity of the process [2]. Large-scale processes are considered to involve products such as ethanol, organic acids, and polysaccharides. Process volumes can exceed $100\,m^3$ per batch and recovery strategies are well-established. Medium-scale processes involve production of robust products such as penicillin or streptomycin. Conventional separation processes may be used, and their cost depends heavily on the cost of the initial volume reduction steps. Small-scale processes involve production of specialty pharmaceuticals and enzymes, some of which may be fragile, thus increasing the cost of the separation. The separation steps involved are usually scaled-up laboratory techniques, even though the process volumes can be $1 - 100\,m^3$ per batch. These small-scale biochemical processes benefit the most from development of new separation techniques or strategies.

The emphasis of this article is placed on separation techniques used in the purification of proteins, including enzymes and antibodies (see also → Enzymes, Chap. 3.2.). These are the most difficult and most costly biochemical separations; many of their details are quite novel. The operations used to purify low molecular mass products, including antibiotics, tend to be conventional separation processes (e.g., distillation and extraction), which are discussed elsewhere. The steps used for separating antibiotics have been developed by the industries involved and are reviewed in [2] (see also → Antibiotics, Chap. 6.).

Table 2 lists separation operations used to recover biomolecules. General reviews of bioseparation operations are also available [3–18].

2. Protein Recovery Considerations

Proteins are composed of sequences of ca. 20 different amino acids, and their molecular masses are typically $10^4 - 5\times10^5$. They have four levels of structure. The *primary structure* refers to the amino acid sequence. The *secondary structure* refers to the short-range conformation of the molecules (e.g., α-helices or β-sheets). The *tertiary structure* refers to the complex three-dimensional structure created by the folding of the long chains of amino acids. The tertiary structure of enzymes and antibodies is responsible for their biological activity. This folding often isolates hydrophobic portions of the protein from the aqueous environment, leaving the charged amino and carboxylic acid groups on the surface. Disruption of this tertiary structure often appears irreversible, resulting in a permanent loss of biological activity and a worthless product. Renaturation is possible in principle, but is not yet fully understood. The *quaternary structure* refers to the manner in which multiple polypeptide chains (subunits) with tertiary structure interact; the best known example is hemoglobin, which is composed of four subunits, each of which is bound to an iron atom.

The tertiary structure of a protein can be disrupted by any change in the environment that alters the interaction between the hydrophilic portions of the protein and the solvent (water). This change may be reversible, as in the case of

Table 2. Summary of biochemical separation operations

Operation	Application	Comments	References
Solids removal			
Filtration	removal of cells or cell debris	rotary vacuum filter most common, often with precoat	[1], [14]
	dewatering of cells prior to lysis	cross-flow configuration reduces cake formation	[19], [20]
Centrifugation	removal of cells or cell debris	size of centrifuge is limited, rpm limited if centrifuge is not continuous flow	[14]
Coagulation/flocculation	removal of cells or cell debris	polyelectrolytes used as flocculants	[14]
Product isolation (volume reduction)			
Evaporation	volume reduction, product must be heat-stable	vacuum drying used to keep temperature low	[12], [21], [22]
Extraction	removal of cells or cell debris (whole-broth processing)	aqueous two-phase polymer systems	[23–26]
	product concentration (proteins, antibiotics, etc.)	aqueous two-phase for proteins, mild organic solvents sometimes containing complexing agents for antibiotics	[18], [23–26]
	affinity separation (proteins)	polymer-bound ligands	[23–26]
Adsorption including ion exchange	whole-broth processing (antibiotics)	adsorbent contacted with fermentation	[1], [16], [17],
		broth without solids removal	[27], [28]
	product concentration (proteins, antibiotics, etc.)	nonspecific adsorption, elution required, gradient elution is popular	[1], [3]
	affinity adsorption (proteins)	specific adsorption, elution required	[1], [3]
Precipitation	volume reduction with partial purification (proteins)	salt, poly(ethylene glycol) added, additive not coprecipitated	[29]
Solubilization	isolation of membrane-bound proteins, which are usually insoluble in water	an empirical laboratory technique, nonionic surfactants usually used	[2], [30–34]
	solubilization of inclusion bodies		[35–37]
Purification (fractionation)			
Chromatography	gel permeation, separation according to molecular mass (proteins)	scaleup problems	[8]
		less specific separation	[3], [16]
	affinity purification (proteins)	highly specific purification	[3], [8]
	other chromatographic methods	any method resulting in differential migration through column	[38]
Electrical separations (proteins)	electrophoresis	small-scale method, thermal convection problems	[3], [39], [40]
	isoelectric focusing	small-scale method, gel process	[3], [41]
	electrodialysis	advantageous for salt removal	[42]
	dielectrophoresis	cell separations	[43]
Ultrafiltration (proteins)	protein concentration, salt removal	cake formation (fouling) is troublesome, cross-flow configuration in hollow fiber devices is popular, diafiltration also possible	[44]
Magnetic separations	separation of proteins adsorbed to magnetic support	magnetic affinity beads used, really an adsorption technique	[45], [46]
	cell separations	red blood cells are paramagnetic	
Polishing			
Crystallization	product obtained as pure solid	from solution, supersaturation involved	[1]
Drying	product obtained as pure solid	solvent must be recovered, protein activity is preserved, temperature must be kept low if proteins involved, freeze-drying (lyophilization) often used	[1], [47], [48]

precipitation with mild organic solvents, ammonium sulfate, or poly(ethylene glycol). Extremes in pH, temperature, or shear, as well as exposure to an air – water interface or a nonpolar solvent, can cause complete unfolding of the chain that usually appears to be irreversible. Therefore, many traditional separation processes, such as extraction into an organic solvent, distillation, and evaporation, often cannot be applied to protein recovery processes.

Although several methods are available for removing solids and concentrating protein solutions, relatively few methods exist for separating proteins from each other. Available methods exploit differences in solubility, charge, and molecular mass. However, the most specific property of a protein used in purification is its tertiary structure and, thus, its biological affinity for certain molecules.

Enzymes, for example, have affinity for the substrates and cofactors in the reactions they catalyze. Since nucleotide cofactors (e.g., nicotinamide – adenine dinucleotide, NAD) are involved in many enzymatic reactions, use of nucleotides in affinity purification is not highly specific for a particular protein. However, a monoclonal antibody raised against a specific enzyme is extremely specific and has affinity for only that enzyme (→ Monoclonal Antibodies).

3. Cell Disruption

Small bioproducts are usually secreted from the cell, making the first separation step (i.e., solids removal) reasonably straightforward. Larger molecules, such as proteins, are not always secreted from the cell. If the product is intracellular, it generally must be released by rupturing (lysing) the cell [12]. The solids (cells) may be concentrated prior to lysis, but another step to remove solids must follow lysis.

Lysis involves the rupture of either a cell wall or cell membrane, or both. Animal cells are surrounded by a lipid – lipoprotein cell membrane and are reasonably easily ruptured. Bacteria and plant cells (including *Escherichia coli* and yeasts, which are commonly used in genetic engineering as hosts for the production of foreign products) have an additional cell wall that is usually composed of polysaccharide.

The cell wall is very difficult to rupture, especially in the case of the yeast *Saccharomyces cerevisiae.* In some cases, rupture poses problems because the desired proteins are located in the periplasmic space between the cell membrane and the cell wall.

Techniques used to lyse microorganisms are summarized in Table 3; see also → Enzymes, Chap. 3.2. Some lysis methods involve mechanical breakage resulting from shear or friction with solid objects. Friction may produce heat, which can denature the protein. Other techniques use a detergent, an enzyme, or a strong base to dissolve the cell wall. However, these treatments may denature certain proteins and also liberate intracellular proteins, including proteases. Proteases attack and inactivate other proteins, causing product loss. Therefore, the lysis technique must be chosen carefully, and initial product isolation should proceed rapidly.

4. Solids Removal

The three main methods of solids removal are filtration, centrifugation, and coagulation/flocculation. Some cells can be separated by magnetic methods (Section 6.3). Solids removal by aqueous two-phase extraction and whole-broth processing are discussed in Sections 5.2.2 and 5.3.1, respectively.

Ultrafiltration is used primarily for the purification and concentration of macromolecules (Chap. 6) but is discussed in this chapter together with filtration because there is extensive overlap between the two techniques (e.g., theory, cake formation, and membrane fouling).

4.1. Filtration and Ultrafiltration

Filtration is a solid – liquid separation in which a pressure difference is applied to force liquid through a filter medium (membrane) that is impermeable to the solid. The product may be a concentrated solid or a clarified liquid. In *ultrafiltration,* a higher pressure is required to separate dissolved macromolecules by forcing the solvent and small solutes through a membrane that is impermeable to the macromolecules. An even higher pressure is required for *reverse osmosis* (hyperfiltration) in order to

Table 3. Lysis of microorganisms ∗

Method	Description	Advantages	Disadvantages
Physical Methods			
Agitation with abrasives (glass beads)	rapid mixing with glass beads used for Brewers yeast, *Saccharomyces cerevisiae*	effective against tough cell walls enzyme activity compares favorably with that obtained by other methods suitable for large-scale enzyme production	removal of glass beads from the disrupted cells
Solid shear (freeze pressing)	pressure extrusion of frozen material through a narrow hole disruption is probably caused by deformation of cells embedded in the ice	particularly advantageous for heat-sensitive enzymes high enzyme yields are obtained high percentage of the cells are lysed	large-scale equipment not commercially available freezing of cells prior to disintegration
Liquid shear	passage of a cell suspension (10 – 17 wt/vol%) through a restricted orifice at pressures of up to 200 MPa	effective for bacterial cells and to a lesser extent fungal cells very popular suitable for large-scale enzyme production	heat generation single-pass operations usually insufficient irregular particle size (filament or pellets) reduces the efficiency of cell breakage
Freeze–thawing	freeze-thawing the suspension at − 20 to − 35 °C ice crystals break cell membrane		most intracellular enzymes defy release most cells are resistant to disruption slow and inefficient
Chemical Methods			
Enzyme treatment	lysis with egg-white lysozyme large-scale lysis with *Micrococcus lysodeikticus* without a strong cell wall, the resulting protoplast or spheroplast lyses because of the high osmotic pressure of the cell contents (5 – 25 kg/cm^2)	gentle and selective	possible destruction of enzyme by cellular proteases expensive enzymes are mixed with the whole cell lysate, which adversely affects subsequent purification steps
Detergent treatment	ionic detergents: sodium dodecyl sulfate and cetyl trimethyl ammonium bromide nonionic detergents: Tween or Triton X-100	effective for the commercial production of cholesterol oxidase	may inactivate enzymes presence of detergents affects subsequent purification
Alkali treatment	pH: (11.5 – 12.5) for 20 – 30 min	inexpensive used to extract the therapeutic enzyme L-asparaginase from *Erwinia chrysanthemi*	may inactivate enzymes reduces pyrogen content
Osmotic shock	rapid change in salt concentration	only low levels of soluble proteins are released, facilitating subsequent purification	tough cell walls are less susceptible to this method cells from solid – liquid recovery steps often contain much occluded salt

∗ Reproduced from [12] with permission of CRC Press.

overcome the osmotic pressure that is created across the membrane due to the impermeability of the membrane to the solute. The applied pressure forces the solvent through the membrane and reverses the direction of osmotic solvent transfer (→ Membranes and Membrane Separations).

Only filtration and ultrafiltration are applicable to biological processes. Filtration is discussed in detail elsewhere (→ Filtration), as is ultrafiltration (→ Membranes and Membrane Separations).

4.1.1. Traditional Filter Operations

Filtration is sometimes used to concentrate whole cells prior to lysis, but most often to re-

move cells from an extracellular product. Two types of filtration are employed in the pharmaceutical industry [1], [14]. The plate and frame arrangement, a batch operation, requires periodic removal of the filter cake (impermeable solids); it is applicable only to small-scale processes. The rotary vacuum (rotary drum) filter, the workhorse of the industry, comprises a filter cloth on a rotating drum so that the cake may be removed continuously and the membrane reused.

Filter cakes tend to be compressible, causing the filtrate flow to decrease with increasing pressure. Even though filtrate flow may drop due to cake formation, increasing the pressure drop is counterproductive for a compressible filter cake. In a rotary vacuum filter, accumulated cake is removed in the latter part of the drum cycle, most commonly by the string-discharge or knife-edge method. The string-discharge method is applicable only to very porous, usually incompressible filter cakes. The knife-edge method is more suitable for denser, compressible cakes [14].

When cake formation is particularly difficult, as in almost all biological applications, *filter aids* can be employed to facilitate cake removal but they also perform several other functions. They help to retain finer particles than the membrane would otherwise allow. Their most common function is to offset the clogging properties of the cake. Cells are deposited on the cake, but reasonable filtrate flow is maintained due to the porosity of the filter aid. A thin layer of the filter aid is removed during cake removal; removal is thus more efficient than scraping the cells from the membrane. The most common filter aids for biological applications are diatomaceous earth, which consists of the skeletal remains of tiny aquatic plants, and perlite, which is a volcanic rock processed into an expanded form. Coagulants and flocculants may also be used to create larger particle aggregates that do not clog the pores of the membrane to the same extent as single particles.

Filter aids must be used with caution, however [14]. Waste cells that are contaminated with filter aids are no longer suitable for animal feeds. If the product is an extracellular enzyme, it may adsorb onto the filter aid. Furthermore, filter aids are costly. Thus, the advantage of a filter aid over decreased filtrate flow should be carefully considered.

Figure 1. Schematic representation of concentration polarization without gel formation (A) and with gel formation (B) ∗

4.1.2. Theory of Ultrafiltration and Cross-Flow Filtration [19], [20], [44]

In ultrafiltration, a pressure difference across a membrane that is impermeable to dissolved macromolecules causes solvent and small solutes to pass through the membrane while the macromolecule is retained. Macromolecular adsorption at the membrane surface fouls the membrane and decreases the permeate flux. This phenomenon is known as *concentration polarization* because diffusion of the macromolecule back into the solution creates a concentration gradient. The macromolecule concentration at the membrane surface often exceeds its solubility limit, and an insoluble gel layer forms. Proteins often exhibit this behavior, which is illustrated in Figure 1. The flow of feed is tangential to the membrane filter (i.e., cross-flow), which minimizes fouling.

Conventional, "dead end" filtration of cells, i.e., filtration involving bulk flow toward the membrane, is associated with the problem of cake formation. Tangential flow (cross-flow) filtration can be employed to reduce cake formation [19], [20]. In principle, this is similar to the ultrafiltration illustrated in Figure 1B, the gel layer representing the filter cake. However, in cross-flow filtration the back-diffusion phenomenon is more correctly termed *particle polarization*.

In both ultrafiltration and cross-flow filtration, the permeate flux J (the volumetric flux of filtrate, $m^3\,m^{-2}\,s^{-1}$), is given by

$$J = \Delta P / R_T$$

where ΔP is the pressure drop and R_T is the total resistance to permeate flow. The parameter R_T is the sum of three effects caused by the membrane, the gel (or cake) layer, and the diffusion layer. In ultrafiltration, the numerator is really $\Delta P - \Delta \Pi$, where $\Delta \Pi$ is the osmotic pressure difference; however, for dilute macromolecular systems, $\Delta \Pi$ is negligible. If quantitative retention of the macromolecule (or particle) and gel (or cake) formation are assumed, then

$$J_{if} = 0;\ \text{i.e.},\ J_{ic} + J_{id} = 0$$

where

J_{if}= molar flux of macromolecules (or particles) in the permeate (given by Fick's law)
J_{ic}= molar flux of macromolecules (or particles) toward the membrane due to flow
J_{id}= molar diffusion flux of macromolecules (or particles) from the membrane

With $J_{ic} = Jc_i$, $J_{id} = -D_i \mathrm{d}c_i/\mathrm{d}x$, and $k_d = D_i/\delta$, then

$$J = k_d \ln (c_{is}/c_{ib})$$

where

c_i= concentration of macromolecules (or particles), g/cm^3
D_i= macromolecule (or particle) diffusivity, cm^2/s
x= length coordinate from membrane or gel surface, cm
k_d= mass transfer coefficient, cm/s
δ= boundary layer thickness, cm
c_{is}= concentration of macromolecules (or particles) at the edge of the gel (or cake) layer, g/cm^3
c_{ib}= bulk feed concentration of macromolecules (or particles), g/cm^3

The parameter k_d is easily predicted by the Graetz solutions for laminar flow or by the Dittus – Boelter correlation for turbulent flow [44].

The above result implies that the gel (or cake) properties, not the characteristics of the membrane, control the resistance to permeate flow. Therefore, the permeate flow can be increased only by reducing the cake (or gel) resistance; this is accomplished by using high shear rates that are produced by operating at high velocities in narrow channels, as predicted by the theoretical dependence of k_d [44]. Furthermore, the permeate flux is independent of pressure. Increasing the pressure results in a brief, transient increase in permeate flux, but the gel (or cake) thickness increases concomitantly, yielding an identical steady-state flux. Finally, the value of k_d must be considered in the decision of whether to use cross-flow filtration or ultrafiltration in a batch or continuous mode [19], [20].

4.1.3. Biological Applications of Ultrafiltration and Cross-Flow Filtration

Cross-flow filtration of whole cells provides high filtration rates by minimizing cake formation

without the need for filter aids or flocculants [19]. The cost of increased filtrate flow is determined by the energy necessary to maintain the cross-flow in excess of that necessary for the transmembrane pressure drop. Cross-flow filtration has been used to separate blood plasma from red blood cells [4]. It should also be suitable for processing cell lysates such that cell debris is retained, but intracellular protein passes into the filtrate [49]. However, cake resistance then appears to be more of a problem because protein is adsorbed onto the cell debris in the cake. Even with large volumes of wash water, protein retention is still a problem. For this process to become economically viable, cake formation must be further minimized. Cross-flow processes are generally carried out in rectangular channels. Attention must be paid to possible shear denaturation of proteins. The design and choice of cross-flow filtration equipment are discussed in [19], [20].

Ultrafiltration is an established procedure for concentrating biological macromolecules. These applications are reviewed elsewhere [44] and include the fractionation of blood and plasma [4] (see also → Membranes and Membrane Separations). Hollow fiber modules are the most popular configurations for ultrafiltration, but other designs are also possible. Important considerations in designing and choosing equipment are described in [50].

Figure 2. Schematic of a continuously operated ultrafiltration membrane reactor ∗
a) One-way valve; b) Pump; c) Ultrafiltration module; d) Ultrafiltration membrane
∗ Reproduced from [44], with permission of Springer Verlag.

A novel concept involving ultrafiltration reactors is illustrated in Figure 2 [44], where substrate is fed continuously into a closed loop containing an enzyme. The enzymatic reaction occurs and the product is removed through the ultrafiltration membrane; the enzyme is retained to react with more substrate. However, shear enzyme denaturation and nonquantitative enzyme retention have been reported in this system [44].

Another novel variation is affinity ultrafiltration, in which the membrane is permeable to free proteins, but impermeable to proteins that are bound to affinity ligands. This allows retention of specific proteins while others pass into the permeate [51].

Diafiltration combines aspects of dialysis and ultrafiltration. Dialysis is a rate process in which macromolecules enclosed by a membrane diffuse more slowly through the membrane than do solvent and small solute molecules. Membranes that are impermeable to macromolecules are available. The solution outside the membrane is exchanged several times to allow effective removal of small solute molecules. Dialysis is a useful laboratory technique. In diafiltration, the filtrate formed in ultrafiltration is continuously replaced with fresh solvent (water) to enhance small solute removal [44].

4.1.4. Additional Methods for Reducing Fouling and Cake Formation

Cross-flow filtration or ultrafiltration does not entirely eliminate cake formation or fouling. Other methods, such as the following, are available.

Promotion of Turbulence. When laminar flow occurs in an entrance region, e.g., in tangential flow processes, the mass-transfer coefficient for particle (or concentration) polarization is proportional to the cube root of the Reynolds number, i.e., $k_d \sim Re^{1/3}$. (The Reynolds number $Re = dV\varrho/\mu$, is a dimensionless velocity, where d is the flow channel diameter or thickness, V is the average or bulk velocity, ϱ is the fluid density, and μ is the fluid viscosity.) In turbulent flow, $k_d \sim Re^{0.8}$. Therefore, caking and fouling in cross-flow filtration and ultrafiltration equipment are often avoided by promoting turbulence, e.g., with static mixer wires placed near the membrane or by fluidization of glass particles [52], [53]. However, any method that induces turbulence also increases the shear rate and can irreversibly denature labile proteins.

Figure 3. Regimes of operation of cross-flow electrofiltration ∗

C_B = bulk feed concentration of macromolecule
C_S = concentration of macromolecule at the membrane
δ = thickness of region of particle polarization (boundary layer)
∗ Reproduced from [55], with permission of McGraw-Hill.

Electrophoresis. Since macromolecules and particles almost always bear a charge that is usually negative, an electric field of appropriate magnitude and polarity applied perpendicular to the membrane should reduce or remove the cake or fouling [54], [55]. This phenomenon is known as electro(ultra)filtration and is illustrated in Figure 3. A critical voltage exists below which electrophoresis is too slow to offset the net flow toward the membrane caused by other mechanisms (Fig. 3A). Above the critical voltage, macromolecules or particles concentrate away from the membrane, resulting in a diffusive flux in the direction of the membrane (Fig. 3C). In this case, increasing the flow decreases the permeate flux by inducing cake formation. At the critical voltage there is no concentration gradient and, hence, no diffusive transport (Fig. 3B). Cake formation and fouling do not occur and increased flow increases permeate flux. Cross-flow electrofiltration has been demonstrated, but not in biological systems. Electro-ultrafiltration has been demonstrated in both nonbiological and biological systems [56].

Radial Migration. The dissolved macromolecules involved in ultrafiltration are too small to exhibit radial migration. However, particles migrate radially across streamlines due to inertia. Migration reduces cake formation and fouling and occurs from regions of high shear to regions of low shear. High-shear regions are found close to solid boundaries, whereas regions of lowest shear are always farthest from a boundary. Radial migration is reviewed in [57].

4.2. Centrifugation

Centrifugation is a well-developed unit operation and is discussed elsewhere (→ Centrifugation, Filtering, → Centrifugation, Sedimenting). Biochemical applications include cell separation from broths, removal of cell debris, separation of protein precipitates, adsorbent recovery, and, if ultracentrifugation is included, separation of dissolved macromolecules. Although standard centrifugation is a batch operation in the laboratory, it may also be a continuous, large-scale operation [14]. Continuous ultracentrifugation is also possible [58], [59].

Several different types of equipment are available for industrial centrifugation, including the tubular bowl, scroll and disk-nozzle arrangements. Basket centrifugation may be used to combine filtration and centrifugation in the same unit. The relative merits of these designs have been evaluated [14].

Centrifugation is limited to removal of particles with significantly higher densities than that of the solvent ($\Delta\varrho > 10^{-3}$ g/cm^3). Larger par-

ticles sediment more rapidly, requiring smaller, lower-speed centrifuges.

Although centrifugation is a reasonably large-scale operation, additional scaleup to handle very large throughputs is limited by the mechanical strength of the materials used to construct centrifuges. Thus, size and speed limitations on large-scale devices exist that do not apply to laboratory-scale devices [14].

4.3. Coagulation and Flocculation

(→ Flocculants)

Coagulation and flocculation are similar and their definitions vary. However, here coagulation is defined as the agglomeration of suspended particles due to the reduction of the repulsive forces caused by surface charge that keeps them separate and suspended in a liquid medium. The repulsive forces are reduced either by addition of inorganic electrolytes, which shield the repulsive surface charges, or by addition of polyelectrolytes that bind to and neutralize the surface charge.

Flocculation is the agglomeration of particles due to the bridging effect exerted by polymers that are adsorbed to more than one particle. Often, both mechanisms occur simultaneously when polymeric polyelectrolytes are involved. Flocculated aggregates tend to be more porous than coagulated aggregates.

Coagulation and flocculation have been applied mainly to removal of whole cells, although, in principle, they can be applied to cell debris and proteins. Particles are often coagulated or flocculated prior to filtration to reduce passage of small noncoagulated particles through the filter cloth (breakthrough) and to produce a more porous cake. For important operating parameters for these largely empirical operations, see [1], [14].

5. Product Isolation

5.1. Evaporation

Evaporation may be used as a volume reduction step in a bioprocess. The principles and equipment that are involved are discussed elsewhere in this volume (→ Evaporation). To minimize protein denaturation, vacuum evaporation may be used. Operating temperatures $< 40\,^{\circ}\mathrm{C}$ are desirable [12]. Foaming often causes equipment fouling and protein denaturation at the air–water interface. Ultrafiltration (Section 4.1.) is a much gentler method of volume reduction for proteins, and has to some extent replaced evaporation.

The most common examples of evaporation operations in bioprocesses are fruit juice concentration and essence recovery processes [60]. The aim of fruit juice concentration is to remove only the water, while retaining the flavor and nutritional components intact. Subsequent addition of water then yields the desired product. Since essential oils are usually more volatile than water, they are removed first and remixed with the product after evaporation of water [21], [22].

5.2. Extraction

Liquid – liquid extraction is a traditional separation operation that can be applied to purification of bioproducts; both organic and aqueous extraction media are used. Antibiotics and other small biomolecules (e.g., amino acids and vitamins) may be soluble in organic phases under certain conditions. Proteins, in general, either are insoluble in organic phases or irreversibly denature upon dissolution in an organic phase. However, extraction between aqueous, two-phase polymer systems provides a method of protein separation.

The equipment used in extraction of biomolecules does not differ substantially from extraction of other compounds and is described in detail elsewhere in this volume (→ Liquid – Liquid Extraction) [23]. However, in aqueous two-phase systems, the closeness in density of the two phases may cause some operating problems.

5.2.1. Organic Solvents

Small biomolecules may partition into organic solvents, such as straight-chain or branched aliphatic alcohols in the C_4–C_6 range and their acetate esters. Subsequent reextraction into an aqueous phase results in significant volume reduction. Many antibiotics contain carboxylic acid groups so that their solubilities change

significantly with pH [61]. Most steroids are more soluble in organic solvents than in aqueous media and, hence, are easily extracted into oil phases. Partition coefficients for these small biomolecules are not readily available however.

The solubility of a small biomolecule (e.g., a vitamin or antibiotic) can be modified by changing its counterion. In these *ion-pair extractions,* the counterion (e.g., a proton) is exchanged with a univalent cation (e.g., a quaternary ammonium ion, RNH_3^+) [18, Chap. 5]. If R is aliphatic, the solubility of the molecule in the organic phase increases as the length of R increases.

Employing *reverse micelles* may permit extraction of proteins into an organic phase, as shown in Figure 4 [62]. Micelles are aggregates of amphiphilic surfactant molecules. In aqueous solutions, the nonpolar tails of the surfactant molecules constitute the core of a usually spherical aggregate, whereas the polar heads face outward. In reverse micelles, the nonpolar tails orient outward in an organic solvent and the polar groups form the core. Proteins can be extracted with some degree of selectivity into the aqueous environment in the core of a reverse micelle, where they are stable. Reextraction into an aqueous phase follows, resulting in significant volume reduction.

Figure 4. Protein solubilization in a reverse micelle ∗
The hydrophilic interior of the reverse micelle shields the enzyme from the organic solvent.
∗ Reproduced from [62], with permission of the American Institute of Chemical Engineers.

Liquid-emulsion membranes permit extraction into an organic phase and subsequent reextraction into an aqueous phase in a single step, as shown in Figure 5. The technology for these membranes is well-established in nonbiological systems and should be applicable to biological systems. Transport through the membrane occurs by means of diffusion and a carrier that is soluble only in the organic phase. Facilitated transport is also possible; cotransport and countertransport mechanisms can move solutes against their concentration gradients, providing a significant increase in concentration. This technology has been used successfully in the laboratory to extract phenylalanine, one of the components of Nutrasweet (aspartame [*2239-47-0*]) [63].

5.2.2. Aqueous Two-Phase Systems [24–26]

Certain water-soluble polymers are mutually incompatible, as are certain polymers and inorganic salts [24], [26]. If these substances are added to water, partitioning occurs to produce a multiphase mixture in which each phase contains a majority of one solute. As many as 18 phases have been documented [24], [26]. Of particular interest for protein separations are two-phase systems involving poly(ethylene glycol) (PEG) with either dextran or a salt. These systems partition into two aqueous phases (water content ≥ 90 %) such that each contains a majority of one component. Poly(ethylene glycol) is always found in the less dense phase. Proteins are soluble in the aqueous phases, and no significant denaturation occurs in the presence of the polymers. Proteins, proteins and cells, or cell debris partition differently between the two phases, providing a basis for separation [24–26].

Removal of Insolubles. In most cases, cells, cell debris, and cell organelles partition preferentially into the more dense phase, and the proteins remain in the less dense poly(ethylene glycol) phase. Therefore, extraction can also be used as a whole-broth processing step (see Section 5.3.1), which eliminates the need for a separate, costly step for removing solids. Ionic strength, polymer type, molecular mass, molecular mass distribution, and the characteristics of the cell or organelle surface are considered to be important for this type of extraction. Prediction of the partition coefficient is not yet possible; experimental measurements are required. Although not often cited, the polymer concentration is an important variable because the length of a tie line is directly related to the polymer concentration and determines the phase volume ratio, which ultimately affects purification. Table 4 presents some data illustrating the degree of partitioning and the yield of some enzymes obtained from cell homogenates.

Several two-phase systems may be suitable for a particular separation. Retention of insolubles at the interface has occasionally been observed; however, this occurs most frequently with whole cells, not cell debris.

Protein Partitioning. Two polymer phases [dextran and poly(ethylene glycol)] are usually used for protein separations rather than a polymer phase and a salt phase. Proteins partition preferentially into the dextran phase in most cases. However, increasing the salt concentration favors partitioning into the poly(ethylene glycol) phase. The exact magnitude of the partition coefficient depends on the type of polymer, its molecular mass, and the ionic strength. For example, increasing the dextran molecular mass favors partitioning into the poly(ethylene glycol) phase. Therefore, as for insolubles, the partition coefficients of proteins must be obtained empirically. Table 5 shows some measured partition coefficients. Partitioning into the poly(ethylene glycol) phase is favored due to the relatively high phosphate concentration.

Table 5. Enzyme partition coefficients in an aqueous two-phase system consisting of poly(ethylene glycol) 4000 (9 wt %), dextran T-500 (2 wt %), and potassium phosphate (0.3 mol/L, pH 7.5) [a]

Enzyme	Volume ratio [b]	K [c]
α-Amylase	8.16	3.64
Glucoamylase	8.60	1.22
Isoleucyl tRNA synthetase	5.86	2.17
α-Glucosidase	6.31	2.84
Glucose 6-phosphate dehydrogenase	8.20	0.62

[a] Adapted from [24], with permission of Academic Press.
[b] Equilibrium volume ratio of less dense to more dense phase.
[c] Enzyme concentration in less dense phase divided by concentration in more dense phase.

The expense of dextran has been a major hindrance to large-scale commercialization of aqueous two-phase systems for protein separations. However, use of cheaper crude dextran rather than purified dextran does not appreciably alter protein partition coefficients.

Since poly(ethylene glycol) is also a precipitating agent for proteins (Section 5.4), care must be taken not to exceed the concentration at which precipitation occurs. Use of poly(ethylene glycol) with a lower molecular mass not only increases the allowable concentration before precipitation occurs, but often increases the partition coefficient in favor of the glycol phase [23].

Affinity and Ion-Exchange Partitioning. Affinity partitioning and ion-exchange partitioning between two phases are alternative protein separation techniques. Both phases should be polymer phases because a salt phase may compromise the binding strength of the protein. Ion-exchange groups can be readily incorporated

Table 4. Partitioning of enzymes from cell homogenates [a]

Microorganism	Enzyme	Two-phase system [c]	K_{enzyme} [b]
Candida boidinii	catalase	PEG 4000–crude dextran	2.95
	formate dehydrogenase	PEG 4000–crude dextran	7.0
		PEG 1000–potassium phosphate	4.9
Sacharomyces cerevisiae	α-glucosidase	PEGH 4000–dextran T-500	2.5
	glucose 6-phosphate dehydrogenase	PEG 1000–potassium phosphate	4.1
Saccharomyces carlsbergensis	α-glucosidase	PEG 4000–dextran T-500	1.5
Escherichia coli	isoleucyl tRNA synthetase	PEG 6000–potassium phosphate	3.6
	phenylalanyl tRNA synthetase	PEG 6000–potassium phosphate	1.7
	fumarase	PEG 1550–potassium phosphate	3.2
	aspartase	PEG 1550–potassium phosphate	5.7

[a] Adapted from [23], with permission of Springer Verlag.
[b] K_{enzyme} is defined as the enzyme concentration in the less dense phase divided by the concentration in the more dense phase.
[c] PEG = poly(ethylene glycol)

into both poly(ethylene glycol) and dextran, but affinity ligands are usually added to the terminal hydroxyl groups of poly(ethylene glycol). Addition of these functionalities does not affect the polymer partitioning as long as the concentration of the derivatized polymer is small [23].

Advantages of affinity partitioning are that a higher degree of ligand use is possible and binding equilibration is more rapid than in fixed-bed processes. Due to the expense of monoclonal antibodies, general affinity ligands such as triazine dyes and nucleotides have been used. The problem of ligand confinement (i.e., recovery and reuse of the ligand) has not been investigated thoroughly, but it depends on the cost of the ligand and the value of the product being purified.

Ion-exchange partitioning is analogous to affinity partitioning. There are only a few documented studies of this phenomenon [23].

5.3. Adsorption Including Ion Exchange

Adsorption is a very common operation in the purification of biological products. The details of adsorption unit operations are presented elsewhere in this volume (→ Adsorption). In this article, only the aspects pertinent to biological separations are discussed, and ion-exchange and affinity adsorption are considered to be specific types of adsorption. These techniques are often termed ion-exchange or affinity chromatography, even though they are not strictly chromatographic operations, but rather adsorption followed by elution.

5.3.1. Sorption Processes

Conventional adsorption (sorption) processes are commonly used as an isolation step in antibiotic purification. Activated carbon, the adsorbent found throughout the chemical process industry, is the traditional adsorbent [1]. Ion-exchange resins, particularly the macroreticular variety, are becoming more popular [64]. Adsorption isotherms usually follow the Freundlich model. Although this type of adsorption is nonspecific, elution yields a smaller volume of solution with a higher product concentration. Fixed-bed operations are most common, but stirred-tank operations are also possible [1].

Whole-Broth Processing. In certain cases, adsorption can be used to combine removal of insolubles and product isolation by adding an adsorbent directly to the unclarified fermentation broth. Screening is used to separate the adsorbent from other insolubles. The advantage of this method is that filtration of the insolubles, an expensive processing step, is not needed. Applications of this concept to ionic antibiotics using ion-exchange adsorbents have been documented [27], [28].

5.3.2. Affinity Adsorption

Proteins may be adsorbed biospecifically on the basis of their interaction with a complementary tertiary structure. This process is termed affinity adsorption and is usually depicted by the "lock

and key" model shown in Figure 6. Since adsorption occurs at specific sites, affinity adsorption usually follows the Langmuir isotherm. An affinity adsorbent may be an antibody (monoclonal), an enzyme cofactor, substrate, inhibitor, or compound with a structure similar to any of these substances. For example, the nucleotide cofactor NAD is involved in many enzymatic reactions and can act as an affinity ligand for any of the associated enzymes. Cibacron Blue F3G-A [*12236-82-7*], a triazine dye with a similar ring structure to a portion of the NAD molecule, is also a good, widely used affinity ligand for these enzymes. Other triazine dyes are also useful in certain cases. Although these adsorbents are not very specific, nonspecific affinity adsorption is still a powerful technique because additional purification can be effected during the elution step. Affinity ligands for various proteins are listed in [65–67]. Many well-developed procedures exist for coupling affinity ligands to solid supports [68]. Some common ligands that are already bound to supports are available commercially.

Figure 6. Schematic of "lock and key" mechanism of affinity binding
The affinity adsorbent retains only those molecules that have a complementary tertiary structure.

Monoclonal antibodies represent the ultimate in specificity, but monoclonal antibody technology is still in its infancy (→ Monoclonal Antibodies). The expense of producing these highly specific affinity ligands has limited their application to certain very expensive pharmaceuticals [69].

Affinity adsorption is most often accomplished in a fixed bed, hence the use of the chromatography nomenclature. However, stirred-tank operations with suspended adsorbent are also possible [3].

5.3.3. Ion-Exchange Adsorption (→ Ion Exchangers)

The adsorbents used in ion-exchange adsorption have ionic groups with easily dissociable counterions. Ionic products, such as proteins, amino acids, or certain antibiotics that carry the same charge as the counterion, adsorb by "exchanging" with the counterion. Clearly, the tendency to bind or elute is a function of the isoelectric point of the protein or the p*K* of the antibiotic, and can be manipulated by altering the pH or ionic strength of the solution.

Table 6. Some commercially available ion-exchange products [e]

Type of product	Ion-exchange groups	
	Anionic	Cationic
Cellulose-based	DEAE [a, b] TEAE [a] QAE [a]	CM [a, b] P [a, b]
Sephacel (spherical cellulose beads)	DEAE [c]	
Sephadex (dextran beads)	DEAE [c] QAE [c]	CM [c] SP [c]
Agarose-based	DEAE [a, c] PEI (polybuffer exchanger)	CM [a, c]
Synthetic polymer based (Trisacryl)	DEAE [d]	CM [d]

Suppliers: [a] Bio-Rad; [b] Whatman; [c] Pharmacia; [d] LKBAbbreviations: CM = carboxymethyl; DEAE = diethyl-aminoethyl; P = phospho; PEI = polyethyleneimino; QAE = diethyl(2-hydroxypropyl)aminoethyl; SP = sulfopropyl; TEAE = triethylaminoethyl; [e] Reproduced from [3] with permission of Springer Verlag.

Ion-exchange adsorption is a very useful product isolation step, and high-capacity ion-exchange media are available commercially. Both fixed-bed and stirred-tank processes are possible [1], [3]. Table 6 lists some of the ion-exchange products traditionally used in the purification of biological molecules. A problem common to all large-scale column operations is

bed compression due to the deformation of the packing material [70]. A new generation of supports now exists that are suitable for all column operations; they are significantly more rigid and resist deformation [71]. Examples are listed in Table 7.

Table 7. Rigid supports for large-scale ion-exchange operations in columns

Support	Suppliers
Porous silica	Pharmacia (Uppsala, Sweden; Piscataway, NJ, USA); Syn Chrom, Inc. (Linden, IN, USA); Toyo Soda (Tokyo, Japan); E. Merck (Darmstadt, FRG); Waters Associates (Milford, MA, USA)
Fractogel (cross-linked vinyl polymer)	Toyo Soda (Tokyo, Japan)
Spheron, Separon (hydroxylated methacrylate polymer)	Lachema (Brno, Czech Rep.)

5.3.4. Elution

The adsorbed product must be removed (eluted) from the adsorbent. This is not difficult in conventional adsorption processes where volume reduction is the goal. However, given the relatively low specificity of ion-exchange and many affinity adsorption processes, ingenious elution methods can provide additional purification. However, in any elution process, care must be exercised to avoid increasing the processing volume.

Gradient Elution. Gradient elution is a very common method in which the concentration of a component of the eluent, usually a salt, is increased with time [3]. The salt concentration can be increased stepwise or continuously, most often linearly. The binding strength in ion exchange is a function of the pH and the salt concentration of the eluent, as well as the isoelectric point of the protein. Thus, proteins with different pI values may be eluted separately by subjecting the adsorbent to a salt gradient. Since a portion of affinity adsorption may be ionic in nature, gradient elution may also be useful in this context. Gradient elution is commonly used if the product contains numerous impurities.

Affinity Elution. Affinity elution employs dissolved ligands to preferentially displace adsorbed proteins [3]. Inexpensive ligands must be used here because they are not immobilized.

Magnetic Fluidization. This elution method, the affinity adsorbent is coated on magnetic beads, so that the beads may be fluidized with a magnetic field [72]. Both adsorption and elution occur by countercurrent solid and liquid flow; the affinity ligand is confined to a closed loop within the system. Magnetic supports have also been proposed as methods for separating solid and liquid phases [45], [46].

5.3.5. Quantitative Aspects

Quantitative analysis suggests that three variables affect the fraction of a species α that is adsorbed in affinity or ion-exchange adsorption:

1) the dissociation equilibrium constant, K_p
2) the total concentration of adsorbed and nonadsorbed substrate, p_t
3) the total concentration of free and bound binding sites, m_t [3].

Table 8 shows results of this analysis. Strong binding requires that α approaches unity.

Table 8. Adsorption parameters *

K_p, mmol/L	p_t, mol/L	m_t, mmol/L	α
0.0001	0.01	0.02	0.99
0.001	0.01	0.02	0.92
0.01	0.01	0.02	0.59
0.1	0.01	0.02	0.16
1.0	0.01	0.02	0.02
0.1	0.1	0.1	0.38
0.1	0.5	0.1	0.16
0.1	0.1	0.5	0.81
0.1	0.1	1.0	0.90
0.1	0.5	1.0	0.85
0.1	1.0	1.0	0.73
0.1	0.1	10.0	0.99

* K_p = dissociation equilibrium constant; p_t = total substrate concentration; m_t = total concentration of binding sites; α = fraction of substrate adsorbed. Adapted from [3], with permission of Springer Verlag.

In affinity adsorption beds, $m_t \approx 0.02$ mmol/L and $p_t \approx 0.01$ mmol/L; hence, for strong binding (i.e., $\alpha \to 1$), $K_p \leq 0.001$ mmol/L [3]. Other analyses confirm this [73].

However, strong binding can also result from increasing m_t and/or p_t. A large portion of the binding strength in ion exchange is probably due to the large concentration of binding

sites. Therefore, even though K_p may exceed 0.001 mmol/L in nonspecific affinity binding, binding can be very strong if the ligand concentration m_t is increased or if, as in the case of a genetically altered culture, p_t is increased.

5.4. Precipitation [29]

Under mild conditions, protein precipitation is reversible and subsequent redissolution restores total activity. Protein precipitation may be either a product isolation step or a purification step. In the former case, precipitation and subsequent redissolution in a smaller volume of water not only reduce processing volume, but the resulting solution also contains mostly dissolved protein, free of other soluble contaminants. In the latter case, the differential solubility of proteins may be used for fractionation.

Proteins can be precipitated by changing the pH or temperature or by adding a mild organic solvent, a salt, a multivalent metal ion, or a nonionic polymer [3], [29].

The precipitation method chosen depends on whether the protein precipitate that is formed can be redissolved without loss of activity, the expense of the precipitating agent and its recovery, and the effects of precipitating agent impurities in the precipitate. Models for aggregation and precipitation, as well as precipitation equipment considerations, are described in [29].

Salting Out. High salt concentration promotes protein aggregation and precipitation. Although the mechanism is not well understood, the salt is thought to remove the water of solution from the protein, thereby reducing protein solubility. The Hofmeister series represents decreasing anion effectiveness: citrate > phosphate > sulfate > acetate ≈ chloride > nitrate > thiocyanate. The salts at the low end of this series cause structural damage to proteins. The high solubility of ammonium sulfate [*7783-20-2*] in water and the position of sulfate in the Hofmeister series make it the most popular choice for salting out proteins.

Metal ions such as Mn^{2+}, Fe^{2+}, Ca^{2+}, Mg^{2+}, Ag^{+} also precipitate proteins. These ions bind to different functional groups of the proteins. They act at much lower concentrations than the ions of the Hofmeister series and are easily removed by ion-exchange adsorption or chelating agents.

pH Adjustment. Proteins are soluble in water due to the interaction of their charged groups with water. Adjustment of the pH to the isoelectric point (pI), i.e., the point at which the protein bears zero net charge, yields minimum solubility. Most proteins have a pI < 7, and the relatively low cost of acids makes pH adjustment with acid a popular method of protein precipitation. However, too much acid or base can cause irreversible denaturation.

Organic Solvents. Addition of a mild organic solvent to an aqueous protein solution reduces the solvent dielectric constant, thereby inducing protein precipitation. The solvent must be completely water miscible; ethanol [*64-17-5*] and acetone [*67-64-1*] are the two most common choices. Solvent precipitation is typically performed at low temperature (< 10 °C) because conformational rigidity then hinders irreversible denaturation.

Temperature. Proteins precipitate and denature at different rates when the temperature is increased. However, some robust proteins are resistant to heat denaturation. Therefore, by subjecting an impure mixture to an elevated temperature for an appropriate period of time, a protein can be purified in solution due to the irreversible denaturation and precipitation of the impurities.

Heat denaturation is a first-order rate process and the rate constant obeys the Arrhenius law. Empirical measurement of the activation energies of the proteins involved is necessary to determine the optimal time and temperature conditions [29].

Polymers and Polyelectrolytes. Nonionic, water-soluble polymers induce protein precipitation by excluding water from the solvation structure of a protein. Poly(ethylene glycol) [*25322-68-3*] is the most widely studied and widely used polymer, but dextrans are also employed. The effect of polymers as precipitating agents can be considered to be similar to partitioning in aqueous two-phase polymer systems (cf. Section 5.2.2).

High poly(ethylene glycol) concentrations are required to precipitate low molecular mass

proteins, whereas low concentrations are required for high molecular mass proteins. Poly(ethylene glycol) with a high molecular mass induces precipitation at a lower concentration than does poly(ethylene glycol) with a low molecular mass. Poly(ethylene glycol) with a maximum molecular mass of ca. 8000 is desirable; concentrations do not usually exceed 20 wt %.

Polyelectrolytes such as poly(acrylic acid), carboxymethyl cellulose, and polyethyleneimines precipitate proteins at a much lower concentration (usually < 0.1 wt %) than nonionic polymers. They act more like flocculants and adsorb to the protein. Thus, polyelectrolytes, unlike poly(ethylene glycol), coprecipitate with the protein and can cause irreversible denaturation. Polyelectrolyte precipitation is used mainly for food proteins, which are quite robust [29].

Affinity Precipitation. Affinity precipitation is used mainly as a laboratory technique [74], although one industrial patent has been reported [75]. This method employs a ligand that is bound to the two ends of a spacer arm consisting of carbon chains that sometimes include nitrogen atoms. Most enzymes are multimeric and usually contain two or four identical subunits, each subunit containing an active site. The spacer arm and ligands can form a large network with the multimeric enzyme, which precipitates due to its large molecular mass. This method has been used to precipitate lactate dehydrogenase with a bis(NAD) ligand [74]:

$$\mathrm{NAD{-}CH_2\,CONHNHCO(CH_2)_4\,CONHNHCOCH_2{-}NAD}$$

5.5. Solubilization

Solubilization is the incorporation of an otherwise insoluble species into solution and may be achieved by using a surfactant (detergent). Surfactants contain polar and nonpolar regions and form aggregates (micelles) to minimize unfavorable hydrocarbon – water interactions. In aqueous solutions, insoluble nonpolar species are incorporated into the hydrophobic core of the micelle and are thus solubilized. In hydrocarbon phases, reverse micelles form, and insoluble polar species can be analogously solubilized by incorporation into the hydrophilic core of the reverse micelle. Reverse-micelle solubilization is used as a product isolation step (see Section 5.2.1) [62].

Solubilization is used in the separation of membrane-bound proteins, which are inherently not very soluble in water [30–34]. After cell lysis, addition of an appropriate surfactant solubilizes the membrane-bound proteins. This technique is employed in the laboratory; no large-scale commercial operations are documented. Selection of surfactants is highly empirical but nonionic surfactants are mostly used, Triton X-100 [*9002-93-1*] being the most common.

A further application of solubilization is in the purification of proteins from insoluble inclusion bodies [35]. Inclusion bodies are formed in recombinant DNA technology when microorganisms, especially *Escherichia coli,* overproduce a particular protein. The nonionic detergent Triton X-100 solubilizes the protein granules in the presence of high urea concentrations (5 – 8 mol/L) [36], [37].

6. Purification

The primary methods for purification of biochemical products are chromatography and electrical separations; magnetic separations are less important. Ultrafiltration is also used to concentrate macromolecules and remove small, dissolved solutes and is discussed in Section 4.1.

6.1. Chromatography

Chromatography is the separation of species due to different migration rates through a stationary medium, which is usually a fixed bed. Gel permeation (filtration) and affinity chromatography are most commonly used for protein separations. Although ion exchange is often associated with the term chromatography, it is most often an adsorption – elution operation and is discussed in Section 5.3.

General principles of chromatography are presented elsewhere (→ Chromatography) and industrial-scale chromatography is described in → Process-Scale Chromatography. Biochemical applications are discussed in this section.

In chromatographic separations, a pulse of solution is applied to the column by injecting it into a large volume of flowing carrier liquid. Separation occurs due to the different migration rates of the dissolved species. As a result of dispersion (zone spreading), each species leaves the fixed bed as a bell-shaped peak. Optimal resolution requires minimal zone spreading and significant differential migration. If there is little differential migration and significant zone spreading, resolution is very small, i.e., separation is poor.

The laboratory workhorse is high-pressure liquid chromatography (HPLC), in which high pressure enhances speed and resolution but throughputs are very small. Fast protein, polypeptide, polynucleotide chromatography (FPLC, Pharmacia) performs rapid separations are possible at moderate pressure, again on a very small scale.

Chromatography is inherently a batch operation and, hence, is not very amenable to scaleup. Attempts have been made at achieving continuous operation, most notably, the continuous annular chromatograph [76]. To avoid problems caused by pressure drop and bed compression effects, industrial scaleup procedures inevitably yield short, fat beds, that are often stacked together [70].

6.1.1. Gel Filtration Chromatography

In gel filtration (gel permeation) chromatography, differential migration of globular proteins is achieved due to differences in molecular mass. The column packing is completely inert; only its pore structure is involved in the separation. Lower molecular mass proteins permeate the pores of the packing material, while larger molecular mass proteins do not and, thus, are eluted first.

Gel filtration does not afford precise separation, however. The best possible separation is exclusion of 90 % of the macromolecules that are 5 – 6 times larger than the macromolecules entering the pores [3]. Therefore, this method is most suitable for separating very large from very small macromolecules.

Gel filtration in chromatographic beds is described in [8]. Table 9 summarizes traditional gel filtration media. More rigid media resist deformation [77], a common problem in large-scale column operations (cf. Table 7).

6.1.2. Affinity Chromatography

In affinity chromatography, differential migration is achieved due to the affinity of proteins for surface-bound ligands. The binding strength (cf. Section 5.3.5) need not be very high due to the large size of the bed. Chromatography beds often have $10^3 - 10^6$ theoretical plates; therefore, even a small difference in affinity can yield good resolution as long as it is not compromised by zone spreading. If binding is too strong the operation ceases to be chromatography and becomes an adsorption – elution operation (cf. Section 5.3).

Affinity ligands must be attached to a support medium that usually contains large pores to avoid gel filtration effects and to maximize usable surface area. More than 75 % of all affinity chromatography is performed on agarose supports (e.g., Biogel A series, Pharmacia Sepharoses, LKB Agaroses) [70]. This is due to the high permeability, low nonspecific adsorption, and chemical stability of agarose. Procedures for coupling affinity ligands to agaroses are well established [68]. The most common has been activation using cyanogen bromide (CN-Br) [*506-68-3*], however, instability of the bond formed with polysaccharides has spawned numerous other techniques [67], [78]. Furthermore, the problem of bed compression in large-scale operations has led to increased use of silica as an affinity support [79].

The choice of an affinity ligand is based on the chemistry involved and the cost as discussed in Section 5.3.2. Protein – ligand pairs are tabulated in the literature [65–67]. Monoclonal antibodies are very expensive to produce and may bind their substrates so strongly that chromatography is not feasible; elution under different conditions may be required [69]. Triazine dyes are inexpensive, but less selective. Nucleotides and other cofactors or coenzymes are more expensive, but more selective.

6.1.3. Quantitative Aspects

Although chromatography is largely an empirical science, quantitative prediction of elution

Table 9. Gel filtration media ∗

Company	Gel code	Gel type	Useful working range for globular molecules, M_r

times and resolution is possible. Two models are usually used: (1) the fixed-bed adsorption theory involving the continuum conservation equations [80], and (2) the equilibrium stage model, in which the fixed bed is modeled as a succession of equilibrium stages [60]. The equilibrium stage model is simpler, but neither predicts the number of theoretical stages required nor is sensitive to the effect of operating conditions. The fixed-bed model is completely rigorous, but difficult to solve analytically and requires numerical solutions.

The interrelationship between the affinity desorption coefficient, ligand concentration, and protein concentration is as important in predicting chromatography performance as it is in adsorption (Section 5.3.5); for a detailed quantitative discussion, see [73].

6.2. Electrical Separations

(→ Electrophoresis)

Electrophoresis and dielectrophoresis form the basis of the electrical separation of biological species. *Electrophoresis* is the migration of a charged species toward an electrode of opposite charge in an applied electric field; monopoles, i.e., permanent charges, define the direction of motion. *Dielectrophoresis* is the migration of a particle toward regions of field nonuniformity in a nonuniform electric field; migration is independent of the sign or existence of a permanent charge and involves uncharged species.

6.2.1. Electrophoresis

Theory. The electrophoretic migration velocity v_E of a particle is directly proportional to the applied electric field:

$$v_E = u_E E$$

where

E = electric field, V/cm
u_E = electrophoretic mobility, $cm^2\,V^{-1}\,s^{-1}$.

The value of u_E for spherical particles depends on (1) the radius of the particle, R and (2) the Debye parameter, which is given by

$$\kappa = \left(8\pi n e^3/\varepsilon k T\right)^{1/2}$$

where $n = 1/2\,\Sigma\, z_i^2\, c_i$

n = solution ionic strength
z_i = valence number of species i
c_i = molar concentration of species i
e = charge on an electron
ε = solvent dielectric constant
k = Boltzmann's constant
T = absolute temperature

When $\kappa R \ll 1$, the Hückel theory applies and $u_E = \varepsilon\xi/4\pi\mu$, where μ is the solvent viscosity and ξ is the zeta potential of the particle. The zeta potential is the potential at the surface of shear of the particle and, for practical purposes, may be considered to be equal to the surface potential. When $\kappa R \gg 1$, the Smoluchowski theory applies and $u_E = \varepsilon\xi/6\pi\mu$. The Hückel theory disregards the deformation of electric field lines by the particle and is only valid for small particles. The Smoluchowski theory assumes that electric field lines are always uniform and parallel to the particle surface; it is valid only for large particles. When $\kappa R \approx 1$, u_E passes through a minimum due to the combination of the retardation and relaxation effects. Analytical solutions are not available for $\kappa R \approx 1$, but computer-generated values exist [81]. For all aqueous systems at room temperature, $\kappa \approx 3 \times 10^8\, n^{1/2}$ cm, n being expressed in mol/L. For proteins in solution at typical ionic strengths ($\geq 10^{-3}$ mol/L), $\kappa R \leq 1$, but the value may be sufficiently close to unity to require a computer-generated result for u_E. For cells at typical ionic strengths ($\geq 10^{-3}$ mol/L), $\kappa R \gg 1$.

Applications. From a practical standpoint, precise values for u_E are not needed for protein separations. It is usually sufficient to know the difference between the isoelectric point (p I) of the protein involved and the pH, and to proceed empirically; (the p I is the pH value at which the protein has zero net charge). Since proteins acquire their charge by ionization of amino and carboxylic acid groups, the difference pI − pH represents both the magnitude of the charge on the protein and its sign. If the pH is less than pI, i.e., pI − pH > 0, then the protein is positively charged. If pI − pH < 0, the protein is negatively charged.

Typical useful values for the applied electric field are in the range of $10^3 - 10^4$ V/m, which can cause significant resistance heating in the solution. Heating creates convection currents, which compromise protein resolution. The magnitude of convection due to heating is quantified by the Rayleigh number *Ra:*

$$Ra = \frac{\varrho\beta\Delta T L^3}{\mu\alpha}$$

where

ϱ = average solution density, g/mL
β = coefficient of volume expansion, K^{-1}
ΔT = temperature difference, K
L = length, cm
μ = solution viscosity, $g\,cm^{-1}\,s^{-1}$
α = thermal diffusivity, cm^2/s

If *Ra* is small, convection is unimportant. Small *Ra* values are obtained if μ is large, as in gel electrophoresis. This technique is a popular analytical tool in the laboratory, but is not

a practical industrial process. A second method is to reduce L by, for example, performing electrophoretic separations through a membrane. In this case L corresponds to the membrane pore diameter, not the overall size of the system. However, systems utilizing this concept are not currently used in industry.

Considerable research has been aimed at developing a device for continuous-flow electrophoresis, a desirable operation for commercial processing, but convection problems have still not been resolved. Practical aspects of electrophoresis are reviewed in [39], [40]. A novel concept combines electrophoresis and gel filtration chromatography to focus components of a mixture of proteins [41].

6.2.2. Isoelectric Focusing and Isotachophoresis

In isoelectric focusing, a pH gradient is established with polymeric ampholytes, which migrate in the direction of the electric field. Proteins migrate until they reach their pI (isoelectric pH), where they carry no net charge. Subsequent protein diffusion in either direction is counteracted by migration back toward the pI, hence the term "focusing". This high-resolution separation method is applicable only to proteins that remain soluble at their pI and do not interact with the ampholytes used to establish the pH gradient [3].

The ampholytes migrate faster than the proteins; thus the pH gradient is established more rapidly than the rate of protein migration.

Isoelectric focusing is not a popular large-scale process because the ampholytes are expensive; separation of the product and the ampholytes also presents a problem. Improvements to materials and methods for establishing the pH gradient have been suggested [82].

Heating is also a problem, and, as in electrophoretic separations, gels are often used. A continuous-flow isoelectric focusing device has been developed for preparative-scale operations, that has minimal convection and good heat dissipation characteristics [83]. A membrane sandwich device, which has discrete pH values in separate compartments, has also been suggested for potential commercial-scale applications [40], [82].

In *isotachophoresis,* the electric field varies as well as the pH. The theory of the method is complex, but it is a potentially valuable preparative separation technique. A few successes have been documented in the laboratory [3].

Figure 7. Principle of electrodialysis ∗
(A) Apparatus: a) Anion-permeable membrane; c) Cation-permeable membrane; ○ = positive ion (e.g., sodium); □ = negative ion (e.g., chloride)
Ion migration under action of electrical current (B) causes salt depletion in alternate compartments and salt enrichment in adjacent ones (C).
∗ Reproduced from [42], with permission of Plenum Press.

6.2.3. Electrodialysis (→ Membranes and Membrane Separations)

In electrodialysis, the electrolyte concentration of a solution is changed by the migration of the electrolytes in an electric field through ion-exchange membranes. Anion-exchange membranes are sandwiched alternately with cation-exchange membranes. Figure 7 illustrates the principles of electrodialysis. The dissociation of water into H^+ and OH^- ions provides the coun-

terions, so that the cation and anion of the electrolyte can migrate in opposite directions toward the anode and cathode, respectively. Due to the arrangement of the membranes, alternate compartments become depleted and enriched in electrolyte.

The major application for electrodialysis is the desalination of water (→ Water) [42], but it can also be used to remove salt from protein solutions, possibly after precipitation. In the arrangement shown in Figure 7C, protein solution is simply filled into the "fresh water" compartment. The ion-exchange membrane is impermeable to the protein, and the salt is then removed from the protein solution as described above.

6.2.4. Dielectrophoresis

Dielectrophoresis is the migration of polarizable material in a nonuniform electric field toward the region of highest field nonuniformity. Unlike electrophoresis, permanent charges are not required and an alternating field can still provide unidirectional migration. Dielectrophoresis is discussed comprehensively in [43].

Dielectrophoresis is still mainly a laboratory curiosity; no industrial applications are documented. However, extensive research on cell migration by means of dielectrophoresis, may lead to applications in cell sorting operations for preparative or characterization purposes.

6.3. Magnetic Separations

In magnetic separations, species with high magnetic susceptibilities migrate to regions of high magnetic field strength. Therefore, magnetic separations are analogous to dielectrophoresis in electrical separations. High magnetic field strengths are required, and the term high gradient magnetic separations (HGMS) is often used.

Three different classes of magnetic properties exist. *Ferromagnets* contain unpaired electrons that create a strong magnetic susceptibility. These include iron, cobalt, nickel, and their oxides, such as magnetite (Fe_3O_4). *Paramagnets* contain unpaired electrons that create a low magnetic susceptibility. Examples include molecules, such as hemoglobin, containing transition metals.

Dimagnets, such as silicon dioxide, graphite, and most organic compounds, contain no unpaired electrons, and in a strict sense are repelled by a magnetic field, although in practice the degree of repulsion may be insignificant [46].

The most common application of magnetic separation for biological species involves coating ferromagnetic particles, usually magnetite, with a polymer that can act as an affinity support. The affinity supports may then be used to separate affinity-bound proteins from impurities by isolating the support magnetically [84]. L-Asparaginase has been isolated in this way [85]. Adsorption beds may also be fluidized magnetically. Collection of red blood cells based on the paramagnetic properties of hemoglobin has also been reported [86]. Reviews on the biotechnological applications of magnetic separations are available [45], [46].

7. Polishing

7.1. Crystallization

Crystallization is often used as a final purification step to produce high-purity antibiotics and other solid consumer products. Products are usually crystallized by lowering the temperature. The goal is usually the dewatering of a pure product. Fractional crystallization is also possible, thereby purifying one material while leaving contaminants in solution. However, phase diagrams necessary for fractional crystallization are not readily available, especially for biological products. Thus, crystallization in the biochemical process industry is very empirical. Advantages of crystallization include operation at a comparatively low temperature thus avoiding protein denaturation, and high product concentrations which keep the cost low [1].

In precipitation, solubility is decreased by a chemical additive, which may coprecipitate. The goal is usually volume reduction by redissolution in a smaller volume of water, or fractionation.

A more detailed description of crystallization and precipitation is presented elsewhere (→ Crystallization and Precipitation).

Figure 8. Extraction of penicillin G potassium salt, based on a 100 m^3 batch giving 3150 kg of penicillin G potassium salt ∗∗
∗ Two or more stages involved. Two Podbielniak D 36 machines can process 100 m^3 in 12 h including cleaning time. Lissolamine A [*57-09-0*], a quaternary ammonium surfactant, acts as an emulsion breaker.
∗∗ Reproduced from [2], with permission of Macmillan Publishers, London and Basingstoke.

Figure 9. Semitechnical-scale example of an aqueous two-phase extraction process for an intracellular enzyme based on a 0.5 m^3 fermentor producing 111 g of enzyme protein ∗∗
The enzyme is separated from poly(ethylene glycol) in the product at the point of use by ultrafiltration.
∗ 1 U = 1 μmol of substrate converted per minute.
∗∗ Reproduced from [2], with permission of Macmillan Publishers, London and Basingstoke.

Figure 10. Typical flowsheet for production of an intracellular enzyme based on a 50 m^3 broth ∗∗
Processing time = 12 h (operating time = 10 h, cleaning time = 2 h). Activity figures are appropriate for amidase.
∗ 1 U = 1 µmol of substrate converted per minute.
∗∗ Reproduced from [2], with permission of Macmillan Publishers, London and Basingstoke.

7.2. Drying

Drying, if used, usually is the final purification step and often follows crystallization. The principles of drying are discussed elsewhere (→ Drying of Solid Materials), and few, if any, features are unique to drying bioproducts. Methods are applicable to pharmaceuticals, food products, or enzymes. Although many enzymes cannot withstand the high temperature associated with spray drying [1], this technique is sometimes applicable, because the ex-

posure time to the increased temperature is usually short. Lyophilization (freeze drying) is used when a high temperature must be avoided [47], [48].

8. Bioseparation Strategies

Biological separations involve numerous separation steps, the processing of large volumes of dilute product, the handling of fragile molecules, the need for a high-purity consumer product, and the need to purify a single component from hundreds of similar components. General strategies for selecting bioseparation processes are treated in [60], [87]. Furthermore, methods for classifying separation operations, which suggest ways of conceiving new separation methods, are available [88], [89].

In planning a bioseparation strategy, the general sequence of operations, (1) removal of insolubles, (2) product isolation, (3) product purification, and (4) polishing, should be maintained. However, if necessary, a step may be eliminated or steps may be combined as in whole-broth processing (Section 5.3.1). One of the major rules in selecting separation sequences is that difficult separations should be performed last. This rule is especially important in view of the large processing volumes involved in bioseparations and the difficulty of protein fractionation.

Most future novel separations and separation sequences will be concerned with proteins (i.e., antibodies, enzymes, and hormones). For example, potential production quantities for bovine growth hormone are so large that improvements in its purification would have a major impact on process economics. Important variables that must be considered when designing a protein separation sequence are as follows:

1) protein characteristics
   - molecular mass
   - isoelectric point (charge)
   - biological affinity
   - solubility
2) process characteristics
   - anticipated impurities and their characteristics
   - denaturation sensitivity to heat or shear
   - product concentration
3) cell characteristics
   - difficulty of cell wall rupture
   - intra- or extracellular product
   - if product is intracellular, is it membrane-bound or located in an inclusion body?

This list is not exhaustive because considerations particular to a given protein may introduce other variables.

Three examples of bioseparations are presented. Figure 8 is a flowsheet for penicillin production. Although the technology involved may be outdated, it illustrates the separation sequence concept. The general processing sequence described above is followed: filtration is used to remove insolubles, extraction and adsorption are used for reducing the processing volume and for purification, and the solid product is finally recovered by centrifugation or filtration. For a high-purity product, subsequent processing is required [2].

Figures 9 and 10 are flowsheets for the production of intracellular enzymes. Both obey the general processing sequence and briefly illustrate the variety of processing sequences from which to choose for biological product recovery. In both processes, centrifugation is used to concentrate the cells and a bead mill is used to rupture them. In Figure 9, aqueous two-phase extraction is used for cell debris removal, volume reduction, and purification. In Figure 10, crossflow filtration is used for cell debris removal, followed by ultrafiltration for volume reduction and precipitation for purification. Further examples are described in [2].

1. Introduction

Objectives of Energy Management. The chemical industry uses energy for *fuel* to provide primary heat and *power* for the operation of various processes. Energy management is concerned with the efficient use of this energy; its primary objective is to reduce operating costs, rather than simply to reduce energy consumption. The purpose of energy management is, therefore, to reduce the total energy requirement of a process per unit of output while reducing the total cost of production (or at least holding it constant). Energy usage for space heating and lighting is insignificant compared to process energy usage, except for some sectors of the fine-chemical industry where all operations are carried out indoors.

Many methods for improving the energy efficiency of processes require an expenditure of either capital investment or manpower or both. The return on such investment through reduced operating costs must be acceptable and worthwhile to the company, and investment in energy-saving measures will normally compete with other investment opportunities. The *payback period* is a simple criterion (although it has many limitations) widely used for a preliminary analysis of investment in energy-saving measures. Payback period is defined as:

$$\text{Payback period} = \frac{\text{Capital required}}{\text{Annual savings}}$$

Most of the methods discussed in this article for improving the energy efficiency of chemical processes are based on established technologies and are realistic in terms of being financially attractive and yielding an acceptable return on investment. Whether or not they should be implemented depends on a detailed technical and economic study of each potential application.

Energy for Feedstocks. The chemical industry uses substantial quantities of energy, mainly in the form of oil and gas, as feedstock for conversion to other products. The efficient chemical conversion of energy feedstocks to higher value products is of great importance, but it is normally considered separately from the

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.b03_12

efficient management of energy used to operate processes. Energy usage in the form of feedstocks is not considered in this article.

Energy Supply and Distribution to Processes. The energy used in processes, either as heat or as power, can be supplied and distributed in several ways:

Heat	Power
Primary	Electricity
Steam systems	Direct drives
Direct firing	(steam turbines)
Electric heating	
Secondary	
Heat recovery	

Energy-Using Operations. Every operation in a chemical process requires energy in some form or other, but for the purposes of energy management, the most important energy-using and energy-intensive operations must be identified. An approximate analysis of the main energy-using operations for the chemical industry as a whole was made by GRANT [1]. A more recent and detailed analysis for the chemical industry in the United Kingdom [2] has identified the main energy-using operations in each sector of the industry and for the industry as a whole; the results are given in Table 1. A wide range of processes was analyzed in each sector, and a similar breakdown of energy usage could be expected for the same sectors in the chemical industry worldwide.

For the industry as a whole, around 71 % of the energy is used to provide heat, and around 29 % to provide power. Heat usage is dominated by three operations: (1) heating of process streams, (2) distillation, and (3) drying. Methods for improving the energy efficiency of these operations are considered in this article.

The main power-using operations involve fluid flow through pumps, compressors, fans, and blowers. The energy efficiency of these operations can be improved with the use of more efficient equipment, better matching of equipment capacity to throughput, and more energy-efficient flow control such as variable-speed drives. These techniques are not considered in detail in this article. The methods are more applicable to large pumps, motors, and other items of equipment. In many plants, energy usage is so widely distributed that the actual use in each item of equipment is small, and in such cases, energy saving through improved equipment is difficult to achieve.

Significant power savings are possible if processes are improved to reduce the flow of process streams (for example, by reducing recycles) or to operate at reduced pressure. An example of the latter approach is given (see Section 8.2).

2. Areas and Levels for Energy Management

2.1. Areas

Energy management is involved in two main areas:

Table 1. Energy use in the chemical industry in the United Kingdom [2]

Operation	Energy use in each sector, %						
	Pharmaceuticals	Dyestuffs and Pigments	Plastics and rubber	Inorganic	Organic	Miscellaneous	Total, all sectors, %
Process heating	36	40	42	52	35	38	40
Evaporation	0	1	3	7	3	3	4
Distillation	15	4	20	2	23	5	13
Drying	3	14	16	17	4	14	10
Space heating	23	3	5	1	1	9	4
Fans and blowers	2	2	3	3	1	2	2
Drive motors	1	3	2	4	1	2	2
Refrigeration	6	3	2	2	8	2	5
Compression	6	4	3	3	16	18	10
Mixing	6	5	2	1	1	2	2
Pumping	2	3	2	7	7	4	6
Comminution	0	18	0	1	0	1	2
Total	*100*	*100*	*100*	*100*	*100*	*100*	*100*

1) energy production and distribution, and
2) energy usage within processes.

The area of energy production and distribution deals with the operation of boilers, furnaces, and electrical generators; with compressed air and nitrogen generation; and with the distribution of steam, electricity, and other services. These matters are important, and good energy management should ensure that services are generated and distributed as efficiently as possible. The methods for this are well-known and are not discussed here.

Once the maximum practical efficiency has been achieved in the supply and distribution of services, the only remaining area for energy saving involves reducing the energy requirements of the process. The greatest potential for more efficient use of energy in the chemical industry will almost always lie in decreasing the process energy requirements and usage, rather than in supplying energy more efficiently to processes. Energy usage within processes should, therefore, be the most important consideration for energy management.

2.2. Levels

Energy management is involved at three main levels:

1) Efficient operation of the existing plant (*good housekeeping* measures)
2) Major improvements to the existing plant (*retrofits* or *revamps*)
3) New plant or process designs

Level 1 is primarily the concern of plant management, and the energy management measures involved in operating plants efficiently are often referred to as good housekeeping measures. Level 2 involves plant management as well as process and plant design. Level 3 involves principally research and development, together with process and plant design. The potential for substantial improvement in energy efficiency increases in going from Level 1 to Level 3, but the necessary capital costs and the time scale to achieve the improvements also increase.

3. Good Housekeeping

Good housekeeping measures cover a wide range of relatively minor measures which generally represent good plant management and operating practice. The difference between good and bad housekeeping typically represents around 10 % of the total process energy usage, but it might be more in extreme cases. A checklist of the most important measures follows:

1) *Steam Systems*
   Reduce leaks
   Improve operation of steam traps
   Increase condensate recovery
   Increase flash steam recovery
   Use lower steam pressure if possible
   Use direct steam for heating if possible
   Improve maintenance of steam ejectors
2) *Insulation*
   Check optimum thickness; increase if necessary
   Ensure flanges and manholes are lagged
   Improve protection from rain and water
   Replace after maintenance
3) *Heat Exchangers*
   Monitor fouling; reduce if possible
   Increase cleaning frequencies
4) *Pumping and Compression*
   Avoid oversizing pumps
   Consider replacing undersize lines and valves
   Consider if flows can be reduced
   Switch off when not required
5) *Electrical Systems*
   Improve power factor; minimize other losses
6) *Compressed Air Systems*
   Use minimum operating pressure
   Use minimum inlet air temperature
   Reduce pressure drops in pipework
   Reduce leaks
7) *Cooling Water Systems*
   Minimize flow
   Consider scope for "cascade" flow through units in series
   Switch off when not required
8) *Vacuum Systems*
   Reduce leaks
   Replace steam ejectors by liquid ring pumps

Although these measures may require relatively little capital expenditure, they can involve significant investments of time and manpower. Most of the measures are not "once-and-for-all," in the

sense, for example, that installing a new heat exchanger for heat recovery is a once-and-for-all measure. Good housekeeping measures, therefore, require regular attention if energy savings are not to be eroded.

4. Audits, Monitoring, and Control

The measurement and control of energy use within processes are interrelated, essential aspects of good energy management.

4.1. Energy Audits

An energy audit is an analysis of energy usage which identifies the main areas, operations, and types of energy used in a process. It should be based on actual plant measurements and data, rather than on whatever process design data might be available. Plants are frequently modified so that the operation is very different from the original design. Also, design data may be inaccurate or optimistic with regard to energy requirements.

In many cases, an audit may involve primarily obtaining accurate heat and mass balances for the process, and the major problems that arise are usually concerned with inadequate instrumentation, particularly for steam flow. For example, electrical power consumption is often better metered and easier to quantify than heat consumption.

An energy audit, normally based on a single set of typical operating conditions, is the essential first step in identifying methods of improving the energy efficiency of a process. The results of the audit should, therefore, be analyzed carefully in order to:

1) develop a better understanding of the process,
2) establish a measure of energy efficiency for the process, and
3) establish targets for improving energy efficiency.

If the results of an energy audit are in close agreement with the process design data, they may provide little further understanding of the process. However, if substantial differences exist, the reasons should be investigated because they will often indicate possible methods of improving energy efficiency.

Figure 1 shows two approaches to establishing targets for improving energy efficiency. In the first, the *top-down approach,* targets are often set in an arbitrary manner based on current energy use. For example, a target might be set as a 10 % reduction in energy usage within two years. This is an easy way to set targets, but it provides little insight into the real potential for energy savings or the manner in which the targeted reduction might be achieved.

Figure 1. Targets for energy savings
A) Top-down approach; B) Bottom-up approach

The second method, the *bottom-up approach,* is to try to identify the minimum practicable energy requirement for the process. This provides an absolute target for improving energy efficiency. This approach requires a thermodynamic analysis to identify first the minimum theoretical energy required for the process route (which may be negative for an exothermic reaction). Then the unavoidable additional energy required to operate a real process with the best available technology must be identified. This may require a mixture of thermodynamics and process engineering techniques.

The latter, more rigorous approach is not yet widely applied to complete chemical processes. However, the rigorous thermodynamic approach, in the form of process integration or *pinch technology* [3], is now being used with considerable success for identifying targets in heat recovery systems (→ Pinch Technology).

4.2. Monitoring and Control

Monitoring refers to the regular, systematic measurement of energy use in relation to production

(rather than the one-shot analysis of usage in an energy audit). A good monitoring and control system requires:

1) good instrumentation,
2) a short time period between measurements (otherwise excessive energy use continues for too long before remedial action is taken),
3) clear norms and targets with which to compare the measured energy usage,
4) knowledge of control action to be taken if energy use exceeds the norm, and
5) control systems to implement the action.

4.3. Energy Usage and Production Levels

In establishing norms and targets with which to compare the measured energy usage, problems may arise in quantifying the effects of (1) variations in product mix, (2) variations in weather, and (3) variations in throughput. Of these, the effect of variations in throughput is often the most important.

A typical relationship between energy consumption and production level is shown in Figure 2. Many chemical processes have relationships of this form. In many cases, plants cannot operate over a wide range of throughputs–particulary single-stream continuous processes–and operation at very low production levels is not possible.

The data can show considerable scatter, and the temptation often arises to fit a regression straight line to all the data points to establish a norm. This should be avoided if possible; a detailed analysis of the data may reveal a more complex and accurate relationship between energy use and production levels.

With relationships between energy usage and production of the form shown in Figure 2, both *fixed* and *variable,* or *output-related, components* exist. This can be seen clearly by extrapolating the energy use to zero production. The fixed component can range from 30 % of the total energy consumption at full output to as to as much as 60 % for some batch processes.

With energy consumption vs. output relationships of this form, the energy consumption per unit of output–the normal measure of energy efficiency–decreases as output increases, as shown in Figure 3. Operation of the plant at high output levels, therefore, usually represents an important method of improving energy efficiency. If required production levels are significantly lower than capacity, then a variety of operating strategies, including campaign operation, should be considered [4].

Figure 2. Energy consumption versus output for a typical process

Figure 3. Energy consumption per unit of output versus output for a typical process

4.4. Batch Processes

Increasing the energy efficiency of batchwise processes through improved technology or process modifications can often be more difficult than for continuous processes. As a simple example, the potential for heat recovery is often more limited in batch processes. The control and operation of batchwise processes is, therefore, particularly important for good energy management. Improved sequencing and control of operations, which reduce batch times and increase throughputs, usually significantly reduce the energy consumption per unit of output [5].

4.5. Advanced Monitoring and Control Systems

The monitoring methods discussed above can be applied by using conventional and existing control systems. The use of modern computer-based monitoring and control systems, which are designed to operate on a plant-wide basis, can yield further major improvements in energy efficiency [6–8]. These systems are designed to supervise the individual programmable controllers that operate the control loops on the plant. The system will extract data from the programmable controller networks and then output set points and controller configuration information. Systems are available which are independent of programmable controller manufacture and can link up with most types of instruments and computers.

The data collected can be manipulated and presented in a form useful to plant managers and operators. For example, the data could be production rates, or energy use and waste. These can be projected on a real or historic time basis, and displayed to show how a plant is performing against targets. Data can be presented in the form of bar charts, graphs, and tables or as values superimposed on a mimic diagram.

The system can be used in a passive role as a monitoring and management tool to assist skilled plant operation by bringing together groups of readings, calculating totals and averages, and indicating trends and optimum operating conditions. The system can also be used as a supervisory control system, for example, by changing set points on programmable controllers.

5. Heat Recovery

Heat recovery is the single most widely used technology for improving energy efficiency in chemical industries. This is to be expected because process heating is by far the most significant energy-consuming operation, accounting for 40 % of the energy used by the industry as a whole and as much as 52 % in the inorganic chemical sector (Table 1). In addition, evaporation, distillation, and drying together account for another 27 % of the energy used by the industry as a whole, and heat recovery is an established method of improving the energy efficiency of these operations (Chaps. 6 and 7).

Sometimes, in attempting to consider heat recovery in a process, the potential for reducing the heat requirements of the process is ignored. Improving a process to use less heat is almost always better than modifying it to recover more heat, and the possibility of reducing heat requirements should always be considered first.

Two interrelated aspects of applying heat recovery to chemical processes are (1) process design and (2) equipment design and selection.

Process design involves determining the process streams between which heat is to be transferred and the amount of heat that is to be transferred; this is also called the "duty" of the heat exchanger. *Equipment design* involves the design or selection of the best heat exchanger for the duty. The criteria for the best exchanger involve capital costs, installation costs, and considerations of all aspects of operability.

The basic design equation for any heat exchanger is an overall heat balance of the form

$$\begin{aligned} Q &= \text{rate of heat transfer from hot stream} \\ &= \text{rate of heat transfer to cold stream} \\ &= UA\Delta T_{\mathrm{m}} \end{aligned} \tag{1}$$

where Q is duty (W), U is the overall heat-transfer coefficient (W m^{-2} K^{-1}), A is the heat transfer area (m^2), ΔT_{m} is the mean temperature difference between the fluids (K).

5.1. Process Design for Heat Recovery

The first stage in the design of a heat recovery system is to identify potential heat sources and heat sinks. Heat sources can be either process streams (e.g., the outlet stream from a reactor) or waste streams (e.g., a flue-gas stream). Heat sinks can be process streams (e.g., a reactor feed) or other streams such as combustion air or boiler feedwater.

The stream data necessary to specify heat sources or heat sinks include the following:

1) stream phase (vapor, liquid, mixture),
2) mass flow rate,
3) temperature,
4) pressure,
5) contaminants and fouling characteristics,
6) corrosion and hazardous characteristics, and
7) variations in flowrate and temperature.

The last parameter is important for continuous processes with significant variations in throughput and for any attempt at heat recovery in batch or semibatch processes.

The next stage in process design is to consider matching heat sources and heat sinks, while taking account of the above parameters and the physical proximity of the streams. (Installed costs of heat exchangers can be many times greater than the purchase costs of the unit, and long piping runs between units are undesirable.)

If a number of hot and cold streams exist between which heat exchange is possible, then the resulting heat-exchanger network can be designed in many different ways. In such cases, the techniques of *process integration* (or *pinch technology*) should be applied to achieve the optimum heat recovery network design, by taking into account the balance between energy savings and capital costs, as well as operability considerations for the network (→ Pinch Technology) [3].

Even for a heat recovery system with only a single heat source and sink, consideration must be given to the optimum economic duty for the exchanger. A preliminary economic analysis should, therefore, be carried out before any detailed design calculations are made.

5.2. Types of Heat Exchanger

When a feasible match between hot and cold streams has been identified, the most appropriate type of heat exchanger for the required duty must be selected. The main types of exchanger are listed in the following according to type of construction (→ Heat Exchange). *Tubular heat exchangers:*

Double pipe∗
Shell-and-tube∗

Plate heat exchangers:

Gasketed$^+$
Spiral$^+$

Extended surface heat exchangers:

Plate – fin$^+$
Tube – fin∗

Regenerative heat exchangers:

Rotary$^+$
Fixed matrix∗

A comprehensive guide to heat-exchanger selection and costs can be found in [3]. The types of heat transfer that can occur in heat recovery and a guide to the most appropriate types of exchanger are given in Table 2.

Table 2. Exchanger selection for types of heat transfer

Type of heat transfer	Type of heat exchanger
Liquid – liquid	tubular, plate
Gas – liquid	extended surface
Gas – boiling liquid	shell-and-tube (waste-heat boiler)
Gas – gas	tubular, plate, regenerative

5.3. Equipment Design

Once a heat recovery duty has been specified and the type of exchanger selected, two interrelated aspects of the detailed equipment design must be considered: (1) thermal design and (2) mechanical design.

Some types of exchanger are normally designed by specialist manufacturers for a duty specified by the purchaser (marked by $^+$ in preceeding list); other types are more normally designed by the user to standard methods and codes (marked by ∗ in preceeding list).

Thermal design involves calculating mean temperature differences and heat-transfer coefficients, and hence the required heat-transfer area. The pressure drop for each stream is usually also calculated at this stage.

Mechanical design involves specifying the required heat-transfer area in terms of equipment details, at least to the extent of providing sufficient detail for exchanger fabrication to appropriate codes and standards.

For example, for a shell-and-tube exchanger, this would involve specifying the diameter, length, layout, and number of tubes; the diameter of the shell; the type and spacing of the shell-side baffles; etc.

The two aspects of thermal and mechanical design are interrelated. Heat-transfer coefficients (or pressure drops) cannot be calculated without a knowledge of the basic mechanical features that affect the geometry of the heat transfer area and the velocity of the fluids. An iterative design procedure is, therefore, necessary.

A preliminary mechanical design is established, based on assumed values of the overall heat-transfer coefficient. The thermal design of this exchanger is then checked by detailed calculation. If the thermal design is not suitable, the mechanical design is amended and the procedure repeated. This is known as a *rating procedure* for heat exchanger design. Comprehensive design procedures can be found in [9].

5.4. Example: Optimum Duty of a Waste-Heat Boiler

Process Description. An effluent gas stream from a reactor at a temperature of 550 °C can be used to generate steam at 0.5 MPa (5 bar) in a waste-heat boiler. The waste-heat boiler can be a vertical shell-and-tube exchanger with the hot gases on the tube side and the steam on the shell side. The following data pertain:

Gas flow rate 10 t/h
Gas specific heat 1.63 kJ kg^{-1} K^{-1}
Estimated overall heat-transfer coefficient in the waste-heat boiler 0.12 kW m^{-2} K^{-1}
For steam at 0.5 MPa (5 bar) raised from boiler feed water at 15 °C: saturation temperature, T_{sat} = 150 °C and increase in enthalpy h_{fg} = 2686 kJ/kg
Operating period 4000 h/a

Cost. The value of the steam raised in the waste-heat boiler is ca. 26 $/t. Approximate purchased costs of shell-and-tube exchangers are available, e.g., in [3]. The installed cost of the exchanger is approximately twice the purchased cost.

Method of Analysis. The optimum economic duty depends on the value of the steam raised in relation to the installed cost of the exchanger. Both of these depend on the gas outlet temperature T. The payback period can be used as a first guide for evaluating the investment.

A range of values of T is chosen, starting with a "base case" in which a short payback period might be expected. Successively larger exchangers are then priced, and the payback period for each incremental investment is calculated until the return on the additional investment is unattractive.

Calculations of Heat-Transfer Areas. The temperature profile in the waste-heat boiler is shown in Figure 4 (for explanation of symbols, see Table 3). From Equation (1):

Table 3. Heat transfer areas for waste-heat boiler*

T, °C	Q, kW	M, kg/s	A, m^2
200	1590	0.589	79
180	1680	0.623	98
170	1720	0.640	113
160	1770	0.657	139

*
T = gas outlet temperature;
Q = duty (rate of heat transfer);
M = rate of steam generation;
A = heat-transfer area.

$$Q = 4.53\,(550 - T)$$
$$= 2.69 \times 10^3 M = 0.12 A \Delta T_{\mathrm{m}}$$

The values M and A have been calculated for a range of T, as shown in Table 3.

Figure 4. Temperature profile in a waste-heat boiler

Calculations of Costs. Based on one year's operation (4000 h), the value of the steam generated is ca. $3.81 \times 10^5 \cdot M$ (in \$/a).

The value of steam generated and the installed cost of the exchanger have been calculated for all four values of T. The payback period for the base-case exchanger, area 79 m^2, was calculated first and then the payback period for the incremental investment in the next three sizes, as shown in Table 4.

Comments. Preliminary analysis showed that heat recovery with a waste-heat boiler is economically attractive. The base-case exchanger has a payback period of only 0.3 year. If, for example, the company criterion for investment in energy saving measures required a payback period of about two years (a fairly common requirement), then the optimum economic gas outlet temperature would be between 170 and 160 °C. Detailed design calculations would be concentrated on conditions in this region.

6. Distillation

Distillation is the most widely used operation in the chemical industry for the separation of mixtures of chemical species (→ Distillation and Rectification). It accounts for around 13 % of the energy usage of the industry as whole, and up to 23 % of the energy usage in some sectors such as organic chemicals (Table 1). A summary of 130 of the most important separations in the chemical industry which are carried out by distillation is given in [10].

The basic process of distillation is the equilibrium flash where a mixture of components is separated into a vapor phase and a liquid phase, with the components partitioned selectively between them. The exact equilibrium compositions of the phases are determined by temperature, pressure, initial composition, and relative volatility of the components. Because the equilibrium concentrations for a single flash are not usually pure enough, many successive equilibria are required to achieve good separation. Thus, distillation is carried out in columns having multiple vapor – liquid stages in succession.

A typical distillation column is shown in Figure 5. Feed enters at some intermediate position. Vapor rising up the column comes in contact with liquid falling down the column. At the bottom, a portion of the liquid is vaporized in a reboiler. Vapor leaving the top of the column is condensed, and a portion is returned to the column as reflux. A temperature gradient is created in the column by the addition of heat in the reboiler and the removal of heat in the condenser – reflux system. The concentration of the components tends to follow the temperature profile, with the lighter components concentrating in the upper (cooler) section of the column

Table 4. Costs and payback period for waste-heat boiler

Exchanger area, m^2	Exchanger cost, 10^3 \$	Value of steam, 10^3 \$	Payback period, a	
79	66.2	224.5	66.2/224.5	= 0.29
98	77.7	237.5	11.5/13.0	= 0.88
113	85.2	243.9	7.5/6.4	= 1.17
139	99.4	250.4	14.2/6.5	= 2.18

and the heavier components concentrating in the lower (hotter) section.

Figure 5. Heat flow in a simple distillation column

The column is filled with either trays or packing material to promote intimate vapor – liquid contact. The effectiveness of the stage contacting equipment is measured by tray efficiency or by the *height of a transfer unit* for packed columns. These can be regarded as the fractional approach to equilibrium that occurs in any one physical tray or packing length.

Distillation is a heat-driven separation process in which the heat input at the reboiler (often steam-heated) flows up the column and is rejected at a lower temperature in the overhead condenser. Methods of improving the energy efficiency of distillation are almost always directed toward reducing the reboiler heat demand, because this represents the major energy requirement. Electrical energy is also necessary for pumping cooling water through condensers and for reflux pumps, but this is usually of minor significance compared with the heat requirements.

6.1. Column Design

For a given separation, the reflux ratio and hence the required heat input decrease as the number of theoretical plates (equilibrium stages) in a column increases. The bounding limits are the minimum number of theoretical plates at total reflux and the minimum reflux with an infinite number of theoretical plates, as shown in Figure 6. Column design represents an optimum balance between the relative cost of energy (operating costs) and the cost of the column and internals (capital cost). Current practice is to design for reflux ratios between 10 and 20 % above the minimum.

Figure 6. Relationship between reflux ratio and number of plates

Regardless of the design reflux ratio, columns are frequently operated at much higher reflux ratios, with a corresponding increase in energy consumption. Control of the reflux ratio represents a major operating parameter.

6.2. Methods of Increasing Energy Efficiency

The methods that can be used to increase the energy efficiency of distillation may be divided into three levels:

1) Better operation and control of existing columns (requiring relatively low costs)
2) Major improvements to existing columns (e.g., new internals, advanced control systems)
3) New designs (e.g., split-tower (multi-effect) distillation)

The first two levels are generally applicable to the existing plant, while the third level is usually worth considering only for new plants.

In addition to these methods which are specific to the distillation column itself, heat recovery from the associated hot streams is an important energy-efficient measure. For example, preheating feed streams with both product streams is common practice.

To evaluate and analyze methods for energy efficiency in distillation, detailed calculations of column operation, including stage-to-stage calculations, are usually necessary (→ Distillation and Rectification, Chap. 7.). Computer programs are now available for the design and simulation of distillation columns, and these greatly facilitate the detailed calculations.

6.3. Control and Operation of Columns

The main variable controlling the energy consumption on an existing column is the *reflux ratio.* A number of other variables can be manipulated to allow a reduction in reflux:

product specification
feed plate location
operating pressure

Product specification should be examined critically. The column product specification is often set slightly higher than the ultimate specification for sale or further processing. This minimizes production of off-specification material during normal operating conditions, at the expense of increased energy usage.

The correct feed-plate location should be used. The feed should enter the column at the point where the composition on the tray closely matches the composition of the feed. If it enters anywhere else, efficiency is lost through blending. Many columns are designed with a number of optimal feed points, and if necessary the feed point can easily be relocated.

For many mixtures, separation is easier at lower pressure because the relative volatility increases with decreasing pressure. Lower pressure operation can, therefore, be used to achieve the same separation at lower reflux ratios. The operating pressure of most columns is set to allow condensation of the overhead vapors with cooling water (or air). Because this limits overhead temperatures to a minimum of ca. 35–40 °C, relatively high pressures may be necessary to condense some of the more volatile components. Opportunities may exist for reducing column pressure when cooling capacity is high due to low ambient temperature. Advanced control systems for such pressure reduction are available, but action can also be taken by alert process operators.

6.4. Column Improvements–Internals

New columns are designed with reflux ratios close to the minimum, but many columns still in use were originally designed for higher reflux ratios. In such cases, energy consumption can be reduced by revamping the column to increase the number of stages. Table 5 is a very rough guideline to the economic feasibility of this approach.

Table 5. Economic feasibility of column improvement

Ratio of actual to minimum reflux	Potential cost savings
> 1.3	good
1.3 to 1.1	possible, worth studying
< 1.1	doubtful

The performance of a distillation column depends on the actual number of stages and the stage efficiency (or the total height of packing and the height of the transfer unit for packed columns). Therefore, for stage columns the number of theoretical stages can be increased by (1) increasing the number of trays by increasing the column height or reducing the tray spacing or (2) replacing existing trays with a more efficient type.

Increasing column height can be very expensive. Reducing tray spacing may be expensive because of the cost of modifying tray supports, and problems due to entrainment may result. In many cases, retraying a column with more efficient contacting devices is the most attractive approach [11]. For packed columns, changing to a packing with improved liquid distribution may be attractive.

Generalizations about tray efficiency (or height of a transfer unit for packing) are difficult

to make because of the dependence on the specific application. A preliminary analysis can be made of the energy savings available at various levels of increased tray efficiency. If the results look attractive, tray and packing suppliers can be approached to determine the maximum feasible increase in efficiency, and a detailed economic analysis is then possible.

6.5. Column Improvements–Control Systems

The control system for a distillation column has two basic functions: to stabilize and to optimize the operation. When applied properly, the control system should ensure the production of products to specification at the minimum cost.

Conventional distillation control systems are designed only for stabilization, relying on operator intervention for any optimization. A conventional system for a two-component fractionator is shown in Figure 7. Product flows are level-controlled. The reflux is set independently at a fixed rate, which is usually conservatively high. Product quality is controlled inferentially by varying the reboiler heat input to hold a constant temperature on some critical tray. This type of system is susceptible to variations in heat balance, which lead to changes in product quality.

Advanced control systems are available that use direct material-balance control, feed-forward control, on-stream product analyzers, and digital computers for optimization. Such systems can give more stable operation, control the column at the optimum operating point, and reduce the need for operator action. They offer considerable potential for reducing energy requirements and operating costs [8, 10].

6.6. New Column Designs

In conventional distillation, each column has its own reboiler and its own condenser, normally water- or air-cooled. Heat supplied to the reboiler is rejected without further use in the condenser. Many methods of making better use of these heat flows are possible, involving new approaches to column design; these include:

heat pumping
split-tower operation

A *heat pump system* can upgrade the heat content of the overhead vapors so that they may be used in the reboiler of the same column. A system based on vapor recompression, using the overhead vapors as the heat pump working fluid, is shown in Figure 8. Although heat pumping can produce significant energy savings, only a limited range of applications offer any prospect of

Figure 7. Conventional control system for a distillation column
TC = Temperature control;
LC = Level control;
FC = Flow control

economic viability. The major criterion is the temperature range in the column, and potential applications are restricted to relatively close-boiling components.

Figure 8. Distillation with vapor recompression

The basic principle of *split-tower distillation* is to increase the thermodynamic efficiency by repeated use of a given quantity of energy (analogous to the repeated use of heat in multi-effect evaporation). One possible application is shown in Figure 9. A series of N towers is operated in parallel with approximately equal feed rates, but each at a different (decreasing) pressure. All the heat is applied to the first column, and its overhead vapors are condensed by reboiling the next column, and so on. The energy requirement for the series is theoretically about $1/N$ times the single-column energy requirement. Although this method offers substantial energy savings, it has many practical constraints and has not yet been applied widely.

7. Drying

Thermal drying of solids accounts for around 10 % of the energy usage in the chemical industry as a whole, and up to 17 % of the energy used in sectors such as inorganics, dyes and pigments, and polymers (Table 1). For further information, see → Drying of Solid Materials.

The three main classes of dryers, depending on the method of heat transfer are

1) *Direct contact* (*convective*) *dryers:* heat transfer by direct contact of the wet solid and a hot gas stream
2) *Indirect contact* (*conduction*) *dryers:* heat transfer to the wet solid through a solid wall

Figure 9. Multi-effect distillation

3) *Microwave or radio-frequency dryers:* heat transfer throughout the wet solid by the action of a high-frequency electric field.

Convective dryers are the most widely used type in the chemical industry. The most common application is the evaporation of water vapor, although dryers that evaporate solvents are used in some pharmaceutical and fine-chemical processes. Dryers evaporating organic solvents are less significant energy users because of the lower latent heat of vaporization of organic solvents compared to water.

7.1. Energy Efficiency of Dryers

The thermal efficiency of dryers is usually defined as the ratio of the heat required for vaporization of the water removed to the heat actually used. For indirect-contact dryers, the efficiency can be close to 100 %, but the efficiency of many convective dryers may be as low as 30 %. With this definition, an efficiency of 100 % does not represent the minimum energy use because efficiencies greater than 100 % are theoretically possible with heat recovery from the exhaust gases.

The primary methods of improving the thermal efficiency of convective dryers are

1) improved operation and control
2) heat recovery from exhaust gases

7.2. Operation and Control of Convective Dryers

The flow rate and inlet temperature of the hot gas stream (normally air) are the main parameters in dryer operation. The heat required for a given duty can be reduced by controlling these parameters, i.e., reducing the air flow rate and increasing the inlet temperature, to minimize the exhaust gas enthalpy per unit mass of water vapor [12, 13].

Dryers that operate at a range of throughputs should have correct conditions throughout the range. When running at less than full capacity, many dryers are operated at excessive air flow rates. Spray dryers, fluidized-bed dryers, and rotary dryers may offer little scope for altering the air flow rate without affecting particle transport characteristics within the dryer, and the air inlet temperature may be the only variable that can be controlled.

The minimum level of instrumentation and control for convective dryers should involve temperature measurement of inlet and outlet air, as well as the use of dampers for flow control. A better approach to optimum operation can be achieved with on-line measurement of exhaust air humidity, and hygrometers are now available which can operate up to 100 °C in dust-free gases.

Further improvements in operation, including the avoidance of overdrying, may be possible with direct on-line measurement of product moisture content. Several techniques are available for this, such as microwave absorption [14], but reliable methods are not yet possible for all applications.

7.3. Heat Recovery from Convective Dryers

Recirculation of a fraction of the exhaust gas stream to the inlet air for the heater represents a form of heat recovery that can yield significant energy savings. While this is a simple concept, the increased moisture content of the hot air entering the dryer means that a higher temperature is necessary to achieve the same drying rate. The capital costs of the ducting and control for air recirculation may be high in some cases.

Heat recovery from the exhaust gas stream by means of heat exchangers can result in substantial energy savings. Preheating the inlet air is the most common use of recovered heat, although in principle the heat can be used for other process streams.

Low outlet gas temperatures and heat-exchanger fouling are practical limitations (apart from the cost of the heat exchanger and associated ductwork) which may restrict heat recovery via heat exchangers.

Fouling of heat-exchanger surfaces by particles in the gas stream can often be a major restriction to heat recovery. For example, exhausts from spray, fluidized bed, and rotary dryers may contain too much dust for heat recovery if a cyclone is the only method of particle removal from the gas stream. More efficient gas

cleaning (e.g., by filtration) may be uneconomical if required only for heat recovery, but may be justifiable for high-value products if significant additional product recovery occurs.

The conventional approach to heat recovery from dryer exhaust gases is aimed primarily at recovering sensible heat, i.e., the temperature of the hot gas stream is decreased without condensing any vapor. The potential for heat recovery is greatly increased if the latent heat of the vapor can also be recovered by cooling the exhaust gas below its dew point. This can be achieved in heat pump systems where the recovered latent heat is upgraded to higher temperatures and used to preheat the inlet air. Although the application of heat pumps to drying is the subject of much research and development work, as yet no evidence exists of proven applications in the chemical industry.

7.4. Microwave and Radio-Frequency Drying

When a product containing water is treated with microwave or radio-frequency electromagnetic radiation, the energy is absorbed mainly by the water molecules. Drying is, therefore, possible without the use of large quantities of heated air, which suggests that energy savings might be possible in many applications. However, power for microwave and radio-frequency drying can be generated at an efficiency of only ca. 17 % on a primary fuel basis [14], so that applications with net energy savings are very limited. The capital cost of microwave or radio-frequency drying is high and has not been justified so far on the basis of energy savings alone. Factors that justify microwave or radio-frequency drying are more likely to involve improved product quality, ease of operation, and increased throughput on existing convective dryers.

7.5. Hybrid Dryers for Batch Processes

The drying of pharmaceuticals and fine chemicals is affected by some special factors, compared to the drying of bulk chemicals. These may include the following:

1) High product value
2) Low throughput
3) Difficulty of handling wet sticky material
4) Moisture to be evaporated includes solvents
5) Use of plant to process different materials

For these duties, the trend is toward the use of hybrid solids-processing equipment, in which more than one operation apart from drying can be performed [15]. Examples are combined filter – dryers and equipment in which crystallization, filtration, washing, and drying operations can all be carried out.

The aim of hybrid equipment is to reduce material losses (e.g., in dryer exhausts), handling problems, and hazards, and to increase throughput and flexibility of plant use. Improved energy efficiency is also a factor, but it is not the only consideration. However, even if energy efficiency is not a primary consideration, changes to equipment which increase the throughput of batch processes usually also increase the energy efficiency of the process as a whole (discussed in Section 4.4).

8. Process Design

For many chemical processes, changes in overall process design or operating conditions offer the greatest potential for reducing energy requirements. Even in "mature" processes, which are well-established and have undergone extensive development, substantial improvements in energy efficiency may still be possible. A good example of this is the ammonia process, which by 1960 was regarded as a mature process. However, since then, considerable efforts in process development have substantially reduced the energy requirements from ca. 70 GJ per ton of ammonia to 30 GJ per ton at present (Fig. 10, see next page); see also → Ammonia, Chap. 4.6. The energy requirements are now beginning to approach the thermodynamic minimum for this process route, which is an absolute limitation on further energy savings. Most other chemical processes still have energy requirements that are far in excess of the theoretical minimum.

Processes can be improved in many ways, and generalizations about how to achieve this are not very meaningful. Each process must be considered in detail to identify potential improvements. However, the following examples are given to

show the improvements that can be achieved through (1) less energy-intensive process conditions and (2) improved conversions in the reactor.

Figure 10. Energy requirements for the ammonia process

8.1. Less Energy-Intensive Process Conditions

If processes can be operated at less extreme conditions of temperature or pressure, then energy requirements may be substantially reduced. An example of this is the production of low-density polyethylene. For many years, standard processes involved polymerization at pressures in the range of 100 – 300 MPa (1000 – 3000 bar), with very high power requirements for compression. Typical total energy requirements for the process were around 15 MJ per kilogram of polymer [16]. Modern processes now use low-pressure gas-phase polymerization at about 0.7 – 2 MPa (7 – 20 bar). The total energy requirement for these processes is ca. 3 MJ per kilogram of polymer (→ Polyolefins) [17].

8.2. Improved Conversions

In many processes, the major energy requirement is for separation. Separation also frequently dominates the capital costs of the process plant. Increased conversions in the reactor, for example, by better and more selective catalysts, may substantially reduce energy requirements for downstream separations.

An example of this is the production of styrene monomer from ethylene and benzene. The reaction has two stages: (1) alkylation to give ethylbenzene, followed by (2) dehydrogenation to styrene. The dehydrogenation does not go to completion, and the products from the reactor are condensed to give a mixture of ethylbenzene, styrene, and other hydrocarbons. Separation of this mixture by distillation–in particular, the styrene – ethylbenzene column–requires most of the energy for the entire process. Improvements in operating conditions and catalysts have increased the conversion to styrene per pass from around 40 % to over 75 %. The effect of this on the styrene – ethylbenzene separation is to reduce column steam requirement from ca. 1.8 kg of steam per kilogram of styrene produced to less than 0.5 kg of steam per kilogram of styrene (→ Styrene) [18].

1. Introduction

The discovery of the pinch principle by Linnhoff has provided engineers with a scientific design methodology which has achieved outstanding results across the range of process industries [1]. The way in which industrial processes are designed and retrofitted has been revolutionized. Using the pinch principle, engineers can obtain a better understanding of the fundamentals of a particular process. Some of the original applications in ICI [2] and Union Carbide [3] showed energy savings and capital savings in new designs. The technology has evolved to incorporate cogeneration schemes [4], to improve plant flexibility [5], [6], increase production capacity [5], and reduce the effect of fouling [7] in both new designs and existing plants.

The early applications were in the oilrefining, petrochemical, and bulk chemical plants, but the technology has also been proved across a wide range of process industries, including pharmaceuticals, food, pulp and paper, cement, brewing, coffee making, and ice-cream and dairy products. Pinch technology has been used in various kinds of processes including batch, semicontinuous, and continuous operations incorporating various operating parameters, such as different feedstocks, seasonal demand fluctuations, multiple utilities, quality constraints, and environmental constraints.

2. Composite Curves and Energy Targets

All processes consist of hot and cold streams. A hot stream is defined as one that requires cooling, and a cold stream as one that requires heating. For any process, a single line can be drawn on a temperature – enthalpy plot which represents either all the hot streams or all the cold streams of the process. A single line representing all the hot streams and a single line representing all the cold streams are called the *hot composite curve* and the *cold composite curve*, respectively.

The construction of a composite curve is illustrated in Figure 1. Two hot streams are shown on a temperature – enthalpy diagram.

Stream 1 is cooled from 200 °C to 100 °C. It has a *CP* (i.e., mass flow rate times specific heat capacity) of 1; therefore, it loses 100 kW of heat. Stream 2 is cooled from 150 °C to 50 °C. It has a *CP* of 2; therefore, it loses 200 kW of heat.

The hot composite curve is produced by simple addition of heat contents over temperature ranges. Between 200 °C and 150 °C, only one stream exists and it has a *CP* of 1. Therefore, the heat loss across that temperature range is 50 kW. Between 150 °C and 100 °C, two hot streams exist, with a total *CP* of 3. The total heat loss from 150 °C to 100 °C is 150 kW. Since the total *CP* from 150 °C to 100 °C is greater than the *CP* from 200 °C to 150 °C, that portion of the hot composite curve becomes flatter in the second temperature range from 150 °C to 100 °C. Be-

10.1002/14356007.b03_13

tween 100 °C and 50 °C, only one stream exists, with a *CP* of 2. Therefore, the total heat loss is 100 kW.

Figure 1. Two hot streams plotted on a temperature – enthalpy diagram

Figure 2 shows the hot composite curve for the problem. The cold composite curve is constructed in the same way. In practical applications the number of streams is generally much greater, but these streams are constructed in exactly the same way. Figure 3 shows the hot and cold composite curves plotted on the same temperature – enthalpy diagram. The diagram represents the total heating and cooling requirements of the process.

Figure 2. Hot composite curve

Along the enthalpy axis the curves overlap. The hot composite curve can be used to heat up the cold composite curve by process-to-process heat exchange. However, at either end an overhang exists such that the top of the cold composite curve needs an external heat source ($Q_{\mathrm{H,\ min}}$) and the bottom of the hot composite curve needs external cooling ($Q_{\mathrm{C,\ min}}$). These are known as the hot and cold *utility targets.*

The point at which the curves come closest to touching is known as the *pinch.* At the pinch the curves are separated by the minimum approach temperature ΔT_{min}. For that value of ΔT_{min}, the region of overlap shows the maximum possible amount of process-to-process heat exchange. Furthermore, $Q_{\mathrm{H,\ min}}$ and $Q_{\mathrm{C,min}}$ are the minimum utility requirements.

Figure 3. Composite curves showing the pinch and the energy targets

3. Pinch Principle

Once the pinch and utility targets of a process have been identified, the three "golden rules" of pinch technology can be applied. The process can be considered as two separate systems (Fig. 4) – a system above the pinch and a system below the pinch. The system above the pinch requires only residual heat and is, therefore, a heat sink, whereas the system below the pinch has heat to reject and is, therefore, a heat source. The three rules are as follows:

1) Heat must not be transferred across the pinch.
2) There must be no outside cooling above the pinch.
3) There must be no outside heating below the pinch.

If the amount of heat traveling across the pinch is α, then an extra amount (α) of hot utility must be supplied and an extra amount of cold utility α is required (Fig. 5). Similarly, any outside cooling of the heat sink and any outside heating of the heat source increases the energy requirements. Thus:

$$T = A - \alpha$$

where

T = target energy consumption,
A = actual energy consumption
α = cross-pinch heat flow

To achieve the energy targets, cross-pinch heat flows must be eliminated.

Figure 4. Schematic representation of the systems above and below the pinch

Figure 5. Heat transfer across the pinch from heat sink to heat source

4. Energy – Capital Tradeoff

The composite curves can be moved anywhere parallel to the enthalpy axis, because the composite curves represent changes in enthalpy between certain temperatures, and not absolute values. Thus, $\Delta T_{\min}$ can be increased or decreased simply by shifting one or both of the composite curves horizontally relative to the other. Vertical movement of the composite curves is not allowed since temperatures are governed by the process.

If $\Delta T_{\min}$ is increased, the overlap decreases and the energy target increases. However, capital cost decreases.

If $\Delta T_{\min}$ decreases, capital cost increases but energy cost decreases. Therefore, a tradeoff between energy and capital and, thus, a cost optimum exists. Figure 6 shows the effect of $\Delta T_{\min}$ on energy, capital, and total cost.

Pinch technology provides the value of $\Delta T_{\min}$ with the minimum total cost prior to design. This is determined by a procedure known as *supertargeting* [8].

Figure 6. Energy cost, capital cost, and total cost plotted against $\Delta T_{\min}$

5. Process Modifications and Applications

The insight into the thermodynamics of the process provided by pinch technology enables an experienced practitioner to identify potentially advantageous process changes. For example, by alteration of the temperatures or pressures, it may be possible to reduce substantially the energy bill without an adverse effect on the product or process. Proper modification of the process also leads to other benefits, such as the removal of bottlenecks and the improvement of process operability.

A systematic search of the data for such opportunities is an essential element in any pinch technology survey. This can be an iterative procedure: once any beneficial changes are highlighted, the composite curves must be redrawn and the minimum energy needs recalculated, which may then open the way to further process changes [3], [9].

Table 1. Savings from some applications of pinch technology ∗

Process description	Savings
Crude oil unit	savings of ca. \$ 1.75×10^6 at 1.6 year payback
Large petrochemical complex manufacturing ethylene, butadiene, HDPE, LDPE, and polypropylene	savings over ca. \$ 7.00×10^6 with paybacks from 12 to 20 months
Tailor-made chemicals, batch process with 30 reactors and over 300 products	savings of ca. \$ 0.45×10^6 at paybacks of 3 months to 3 years
Sulfur-based speciality chemicals, batch and continuous	30 % savings to total site energy bill (worth ca. \$ 0.18×10^6 at paybacks of 9 – 16 months
Edible oil refinery, batch operation, wide range of feedstocks	savings of 70 % of process energy equivalent to ca. \$ 0.79×10^6 with paybacks from 12 to 18 months and debottlenecking equivalent to 15 % increased capacity
Batch processing of dairy products and dried beverages	savings of 30 % (equivalent to ca. \$ 0.20×10^6) with payback of less than 1 year
Brewery	savings from 12 % to 25 % of energy costs with paybacks from 9 months to 2 years
"State-of-the-art" whisky distillery	significant debottlenecking and savings of ca. \$ 0.35×10^6 with paybacks from 18 months to 2 years
Paper mill	savings of 8 – 20 % of energy bill at paybacks from 1 to 3 years
Continuous cellulose acetate processing	savings of ca. \$ 0.28×10^6 at 1 year payback
Continuous dry cement process	large energy savings

∗ Savings mentioned above are concerned primarily with energy costs. The majority of the companies also benefited from increased throughput and improved process flexibility and operability; the economic value of these benefits is not included in the table above.

Since 1983, pinch technology has achieved energy savings in the range of 10 – 70 %, reductions in the capital cost of new plants by up to 25 %, increased process capacity by the removal of bottlenecks, and greater flexibility and operability. The projects summarized in Table 1 indicate the variety of industries in which pinch technology has been successfully applied: food, paper, dairy products, whisky, cement, speciality and bulk chemicals, and oil refining. To date, the projects identified by pinch technology have been implemented, in whole or part, in all instances mentioned in Table 1.

5.1. Batch Processes

In the early days pinch technology achieved its most impressive results in continuous processes, but Table 1 includes a number of processes with exceptionally successful studies in batch operations. The key to applying pinch technology in noncontinuous processes lies in the data extraction. There are no shortcuts; detailed measurements and timings of all the process streams are essential if cost-saving opportunities are to be found. Where the technology has been applied to existing operations, there have frequently been wider process benefits, as well as lower energy bills. By improved integration of the plant, capacity has often been increased, without adversely affecting operability [10].

5.2. Cogeneration

The principles governing the correct siting of cogeneration systems were established several years ago [11], [12]. A pinch study uncovers opportunities for introducing such equipment or optimizing existing units.

In the pulp and paper industries, for example, power generation is an important element, and pinch technology has been applied successfully to improve performance and to evaluate alternatives. Some of the examples in Table 1 feature the use of cogeneration schemes.

5.3. Flexibility

A well-integrated plant need not be less flexible [5], [6]. In fact, the opposite is the case, with techniques having been developed to ensure that flexibility is incorporated into the process design in the most cost-effective way. For example, it is possible to allow for changes in feedstock and product specifications, turndown requirements, and seasonal variations.

In a study for Shell, UK, where flexibility was of paramount importance, an integrated design was produced that included twelve operating modes [13]. Throughput was also increased

Figure 7. Example of a process flow diagram
a) Fractionation column; b) Furnace; c) Reactor; d) Stabilizer column; e) Benzene column; f) Toluene column

and energy savings of ca. $\$ 2 \times 10^6$ were achieved within a 1.6 year payback period.

Figure 8. Original flow diagram of distillery cooker system

6. Specific Examples

The two examples that follow give some indication of the way in which pinch technology is applied to specific problems and help to show why it has had such an impact on every industry that has used it.

6.1. Modification of a Continuous Process

Figure 7 shows a simplified flow sheet of an organic chemicals plant. The crude feed is separated into residue and light aromatic fractions, which are mixed with a preheated hydrogen-rich stream before entering the main reactor. The reactor product is cooled and partially separated before being fed to the first of a series of three distillation columns, each fitted with a reboiler and a condenser.

The pinch analysis without process modifications showed that the utility energy target was 22 % lower than the actual use. The pinch point occurred at 150 °C on the hot curve.

When the aspect of process modification was included, it was obvious that on all four of the columns (the initial fractionation column and the three distillation columns), the reboiler temperature was above the pinch and the condenser temperature was below it. If the possibility existed to reduce the reboiler temperature to below 150 °C, where excess heat is readily available, then the requirement for heating above the pinch would be correspondingly reduced, thus offering significant savings. In fact, practical considerations limited the scope for this change, but change was achieved on one of the columns by a reduction of the operating pressure.

The next step was to examine the furnace, which supplied most of the process heating. The flue gas exit temperature was well above 150 °C; therefore, recovery of this heat above 150 °C would reduce the heating target. After composite curves had been redrawn and process modifications incorporated, the revised energy target was less than half the former energy use.

The implementation of these proposals produced an integrated design that used 45 % less energy than before, with the investment that was involved being paid for in less than one year.

Figure 9. Distillery cooker system after integration
a) Water tank; b) Cooker, c) Buffer tank; d) Interchanger; e) Fermenter

6.2. Integration of a Batch Operation

The batch cooking operation in a distillery is shown in Figure 8. Preheated water and grain are cooked by steam injection; cooling begins by venting steam at above atmospheric pressure to the water preheat tank and is then speeded by a steam ejector that evaporates water from the cooker under vacuum. The cooled batch then moves to the fermentation stage.

The pinch analysis of the distillery as a whole had identified the pinch point at 90 °C, which meant that a substantial cross-pinch heat transfer existed within the batch cooking process. Vent steam hotter than the pinch was heating the process water below it, and the ejector exhaust steam was being condensed by cooling water.

The cross-pinch heat transfer was eliminated by a series of modifications. By introduction of a buffer tank between the cooker and the fermenter, the process water could be preheated from the cooling cooked grain, which was below the 90 °C pinch, thus eliminating the inappropriate steam ejector. The vent steam, no longer needed for preheating the process water, was utilized elsewhere on the site to reduce the need for steam to be brought in. The resulting energy savings were only part of the benefit; the cooking cycle was shortened because the cooling was faster and, thus, a process bottleneck was removed and the production capacity of the plant increased. The revised design of the batch cooker is shown in Figure 9.

3.2. Fuel Cells

[Top of Page]

1. Introduction

Combustion is the major source of the energy which drives our technological societies as well as being the principal source of air pollution. Direct combustion is a vast global activity and constitutes the basis for a large number of industries, including transportation, power generation, and heating. Collectively these activities represent a significant fraction of the world gross product.

Technically, combustion is the self-sustaining, exothermic interaction of a fuel with an oxidant through a series of chemical and physical events, ultimately resulting in the formation of water and carbon dioxide, which are the most stable reaction products. In this article, conventional combustion is defined as oxidation of fuel with formation of flames. Our everyday encounters with combustion are mostly subsonic events or deflagrations, in which combustion reaction waves propagate below the speed of sound. However, supersonic combustion events or detonations, in which wave propagation speeds exceed the speed of sound, also exist [1]. Probably the most extensive source of information on combustion is the *Proceedings of the International Symposium on Combustion*, which is regularly published by the Combustion Institute [2]. Information on combustion processes can also be found in the general references. Flameless or nonconventional combustion reactions are accomplished by means of catalysts, such as in catalytic combustion and in fuel cells.

Fuels for combustion are primarily based on fossil hydrocarbons such as natural gas (methane, ethane, and propane), petroleum products (gasoline, diesel, jet fuel, fuel oil), and coal and coal products (synthetic liquid and gaseous fuels). The oxidant is generally oxygen from the air because of its abundance, but there are exceptions. For example, hydrogen and pure oxygen are used in rocket propulsion and in fuel cells. Alternatively, the fuel and the oxidant can be part of the same molecule, as in explosives (e.g., TNT) and solid propellants [1].

The availability and importance of fossil fuels has changed with time. Coal was the dominant fuel in the early 1900s, replacing wood. The discovery and processing of petroleum significantly changed this picture, so that today, for example, transportation almost entirely depends on petroleum products. However, electric power generation by coal combustion continues to dominate. Natural gas, although initially dismissed as an energy resource, is now recognized to be one of the most abundant fuels; it is used largely for residential heating and cooking.

In Figure 1, the role of fossil fuels and therefore combustion in the global energy portfolio are shown. Combustion of coal, oil, and gas collectively provide nearly 80 % of world energy demand. Based on the projections in Figure 2, these fossil fuels, and hence combustion, are expected to maintain their dominant position for the next several decades.

Figure 2. Outlook for total primary energy supply in Mtoe units (1 Mtoe unit = 16.3 GJ). ** Other includes geothermal, solar, wind, etc. Source: International Energy Agency, www.iea.com.

Emissions from combustion processes are the result of many factors, ranging from the type and composition of fuels to the designs of combustion systems to the additives that may be introduced. These emissions can be categorized into nonpolluting (desired) and polluting (undesired). The desired emissions are carbon dioxide (CO_2) and water (H_2O), whereas the undesired emissions include unburned fuel; nitrogen oxides (NO, NO_2, and N_2O, collectively referred to as NO_x), sulfur oxides (SO_2 and SO_3, or SO_x); and products of incomplete combustion (PIC), which include carbon monoxide (CO) and unburned hydrocarbons (UHC). Other PICs are volatile organic compounds (VOC, such as ethane, ethylene, propane, acetylene and solvents), aromatics, polycyclic aromatic hydrocarbons (PAH), and particulates (solid carbon or soot). Other combustion byproducts include formaldehyde, halogenated compounds, and metals. Although the relative amounts of these pollutants formed are small, their impact on urban environments can be significant due to the large-scale utilization of combustion. In fact, most air-pollution episodes in urban areas today are directly attributable to the pollutant emissions from combustion devices and their subsequent atmospheric reactions [3]. In the USA, National Ambient Air Quality Standards (NAAQS) have been set for a number of pollutants generated by combustion processes (Table 1).

Table 1. Major air pollutants and U.S. national ambient air quality standards (NAAQS)

Pollutant	Major Sources	NAAQS[a] & comments
Carbon dioxide (CO_2)	All combustion sources	Possibly injurious to health at concentrations greater than 5000 ppm over 2 – 8 h; atmospheric levels have increased from a preindustrial level of about 280 ppm to over 350 ppm in the 1990s, and the rate of increase has accelerated.
Carbon monoxide (CO)	Motor-vehicle exhaust; some industrial processes	NAAQS for CO: 9 ppm (10 mg/m^3) over 8 h (P), 35 ppm (40 mg/m^3) over 1 h (P), no more than once per year (for both)
Nitrogen oxides (NO, NO_2)	Motor-vehicle exhaust; heat and power generation; nitric acid; explosives; fertilizer plants	NAAQS for NO_2: 0.053 ppm (100 µg/m^3) over a year (P & S); react with hydrocarbons and sunlight to form photochemical oxidants
Sulfur oxides (SO_2, SO_3)	Heat- and power-generation facilities that use oil or coal containing sulfur; sulfuric acid plants	NAAQS for SO_2: 0.03 ppm (80 µg/m^3) over a year (P), 0.14 ppm (365 µg/m^3) over 24 h no more than once per year (P), 0.5 ppm (1300 µg/m^3) over 3 h (S)
Volatile organic compounds (VOC; include ethane, ethylene, acetylene, propane, butanes, pentanes, aldehydes, ketones,	Motor-vehicle emissions; solvent evaporation; industrial processes; solid-waste disposal; fuel combustion; petroleum refineries; gasoline stations;	React with nitrogen oxides and sunlight to form photochemical oxidants. Some VOCs, such as formaldehyde and benzene, are also hazardous to health.

solvents)	dry cleaners; printing; many paints	
Photochemical oxidants (primarily ozone (O_3); also peroxyacetyl nitrate (PAN) and aldehydes)	Formed in the atmosphere by reactions of nitrogen oxides, hydrocarbons, and sunlight	NAAQS for O_3: 0.12 ppm (235 μg/m^3) over 1 h[b] (P & S) no more than one day per year, 0.8 ppm (157 mg/m^3) over 8 h (P & S)
Air toxics (includes benzene, PAHs, vinyl chloride, formaldehyde, beryllium, inorganic arsenic, mercury, asbestos)	Specific types of chemical processes; coke ovens; building demolition	Typically cause cancer or are mutagenic or are hazardous to unborn infants, or cause neurological disorders. Current levels of emission may result in 1000 – 3000 cancer deaths each year.
Suspended particulate matter (PM10: particulate matter less than 10 μm in diameter; PM 2.5: particulate matter less than 2.5 μm in diameter)	Motor-vehicle exhaust; industrial processes; refuse incineration; heat and power generation; reaction of pollutant gases in the atmosphere	NAAQS for PM10: 50 μg/m^3 over a year (P & S), 150 μg/m^3 over 24 h no more than once per year (P & S); NAAQS for PM2.5: 15 μg/m^3 over a year (P & S), 65 μg/m^3 over 24 h no more than once per year (P & S); composed of carbon, nitrates, sulfates, and many elements including lead, copper, iron, and zinc
Lead (Pb)	Motor-vehicle exhaust; lead smelters; battery plants	NAAQS for Pb: 1.5 μg/m^3 over 3 months (P & S)

[a] P: primary (to protect public health), S: secondary (to protect public welfare).
[b] The ozone 1 h standard applies only to areas designated as nonattainment areas when the new ozone 8 h standard was adopted in July 1997.

Although carbon dioxide is a major desired product of combustion of fossil fuels, it is also a recognized greenhouse gas. Carbon dioxide together with other greenhouse gases, such as methane, absorb the infrared radiation reflected by the earth, resulting in a net increase of the energy deposited on earth by the sun and an increase in atmospheric temperature. Therefore, CO_2 emissions have become a global issue, especially after the 1997 Kyoto Protocol [4]. In Figure 3, combustion-generated CO_2 emissions are presented for each of the major fossil fuels. The CO_2 emissions are region-specific, with OECD nations generating nearly 50 % of global CO_2 emissions (Fig. 4). It is likely that in the future, CO_2 emissions will decrease from OECD nations and increase from non-OECD nations.

CO is a flammable, colorless, odorless, and tasteless gas that is produced as a result of incomplete combustion of carbon-containing materials. CO is formed whenever carbon or substances containing carbon are burned with an insufficient oxygen supply. Even when the amount of oxygen is theoretically sufficient, the reaction is not always complete, so that the combustion gases contain some free oxygen and some CO. Incomplete combustion is especially probable when it takes place quickly, as in an automobile engine. CO is a major source of indoor air pollution, and it is categorized as a toxic gas because exposure to CO reduces the ability of the blood to carry oxygen.

NO_x, a mixture of nitric oxide (NO) and nitrogen dioxide (NO_2), is produced by most flame-combustion processes. Both molecular nitrogen in the atmosphere and chemically bound nitrogen in materials being burned can react with oxygen to form thermal NO_x and fuel NO_x, respectively. In general, the formation of NO increases with increasing temperature, while the formation of NO_2 decreases with increasing temperature. At common combustion temperatures, most of the primary emissions of NO_x are in the form of NO. As it is emitted into the atmosphere, smaller amounts of NO_2 are formed by further oxidation of NO. However, more than 90 % of the exhaust NO_x is still NO. In the atmosphere, a mixture of NO_x (mainly NO) and hydrocarbons (mainly VOCs) undergo photochemical reactions in ultraviolet light from the sun to form such secondary pollutants as ozone. Ozone in the upper atmosphere is beneficial because the O_3 layer helps protect us from the sun's dangerous ultraviolet rays. However, O_3 at ground level is quite the opposite because of its reactivity.

SO_x emissions are produced by combustion of sulfur-containing materials, such as coal. More than 90 % of the exhaust SO_x from combustors is in the form of sulfur dioxide (SO_2). In the atmosphere, SO_2 can be oxidized by O_3 and hydrogen peroxide (H_2O_2) with sunlight to form sulfur trioxide (SO_3) as a secondary pollutant. Both SO_2 and SO_3 have high solubilities in water. Therefore, in the atmosphere SO_x dissolves in water droplets to form sulfuric acid (acid rain).

Volatile organic compounds (VOCs), defined as any volatile compounds of carbon that include ethane, ethylene, acetylene, propane, butanes, and pentanes, but exclude methane, carbon monoxide, carbon dioxide, carbonic acid, metal carbides and carbonates, and ammonium carbonate, are produced by incomplete combustion of carbon-containing fuels or unburned fuels themselves. VOCs react with NO_x in sunlight to form ground-level ozone and photochemical smog.

Polycyclic aromatic hydrocarbons (PAHs) are trace products formed by the incomplete combustion of fossil fuels or other organic substances (e.g., tobacco) and are believed to be precursors for soot formation. PAHs are a group of more than 100 different compounds that include at least two aromatic rings in their structures. Some PAHs are potent carcinogens. Atmospheric PAHs have various forms; for example, highly volatile naphthalene (two-ring) exists in the gas phase, benzo[*a*] pyrene (five-ring) exists as solid absorbed on the surfaces of fine particles, and semivolatile phenanthrene (three-ring), pyrene (four-ring), and fluoranthene (four-ring) are distributed between the gas and solid phases. The mechanisms of formation and abatement of various combustion-generated pollutants are discussed further below.

Controlled conventional combustion processes occur in specially designed reactors or “chambers” that can withstand the high temperatures produced. Some examples of these chambers are cylinders in automotive internal combustion engines, and high-temperature alloy tubes or “cans” in energy-producing systems such as gas turbines and furnaces. It is the task of combustion engineers to design these chambers that can operate under demanding thermal conditions for extended periods. Nonconventional combustion processes operate at temperatures significantly lower than flames. For example, hydrogen-air fuel cells operate at about 80 °C while hydrogen-air flames can achieve temperatures of nearly 2000 °C. Catalytic combustors operate at about 800 °C and allow the processing of fuels over a broader temperature window than flames.

[Top of Page]

2. Conventional Combustion

Conventional combustion is defined as a gas-phase reaction involving the creation of a flame in which a fuel reacts with oxygen according to the stoichiometry given in Equation (1).

$$C_xH_y + (x + y/4)O_2 \rightarrow xCO_2 + y/2\,H_2O \qquad (1)$$

The source of O_2 is generally air, which contains about 21 % O_2 and 79 % N_2. This nitrogen dilution reduces the attainable flame temperature and also serves as the source of pollutants such as NO_x. Conventional uses of combustion are broad and range from production of energy and materials to waste-disposal processes. In manufacturing, the major use of combustion is to liberate the energy stored in the reactants to generate heat. The heat is used directly or indirectly. Some direct uses of heat include home/residential heating and drying processes such as for the paper industry, petroleum refining, and iron smelting. Indirect uses are for power generation, where the heat is converted to mechanical or electrical energy by specially designed systems. Combustion of gasoline produces heat, which is converted into mechanical energy by expanding gases in the automotive engine cylinder, which in turn produces a force on a piston. The piston then turns a drive shaft and thus heat is converted to mechanical energy for propulsion of a car. For production of electrical energy, a common system is a gas turbine, in which natural gas or diesel fuel is combusted to generate heat to expand gases, which are then passed trough a turbine producing work to turn a shaft connected to an electrical generator, thus converting the heat to mechanical energy and then to electrical energy. Combustion reactions are also exploited to manufacture materials such as carbon black, metal oxides, and ceramic powders [5-7].

Destructive uses of combustion besides as explosives are primarily limited to the field of incineration, where the combustion process is used to break down toxic materials into less toxic or benign ones so that the reaction products can be more easily disposed of [8], [9]. A significant complication encountered in incineration is the presence of heteroatoms. Unlike hydrocarbon fuels, which primarily consist of C, H, and O atoms, process waste streams can contain heteroatoms such as halogens, nitrogen, sulfur, phosphorus, metals, etc. The ultimate fate of these elements, i.e., their partition among different combustion products, depends on the combustion conditions, and will influence the subsequent air pollution control equipment needed to meet emission standards.

Flames can be categorized into two major groups: premixed flames and diffusion flames. Examples of these flames are the blue flames used in domestic gas-stove cooking and candle flames, respectively. In premixed flames the fuel and oxidizer are mixed at the molecular level, and the relative amounts of the reactants are described by the equivalence ratio Φ, defined by Equation (2).

$$\phi = (\text{fuel amount/oxidant amount})_{\text{actual}}/(\text{fuel amount/oxidant amount})_{\text{stiochiometric}} \qquad (2)$$

Based on this definition $\Phi > 1$ represents fuel-rich and $\Phi < 1$ fuel-lean, conditions. Premixed systems generally have lower and upper flammability limits, i.e., equivalence ratios within which self-sustaining flame combustion occurs. As expected, flame temperatures T_f first increase and then decrease as a function of increasing equivalence ratio, exhibiting a maxima around the stoichiometric conditions, i.e., $\Phi = 1$ (Fig. 5). The presence of excess air and excess fuel at lower and higher equivalence ratios, respectively, limits the maximum attainable flame temperature. Premixed systems also exhibit a unique combustion wave propagation velocity V_f which varies with equivalence ratio in a similar manner to temperature. Since increased flame temperature and velocity correspond to increased intensity of combustion, the formation and emission of

UHC mirror these variables, as shown in Figure 5. The NO_x quantities produced in flames generally follow the temperature pattern for a combination of thermodynamic and kinetic reasons discussed below.

Figure 5. Effects of equivalence ratio on flame temperature T_f, flame velocity V_f, NO, UHC, and CO

In many practical applications that exploit diffusion flames, the fuel and the oxidant are brought together just before combustion for safety reasons, i.e., large-scale premixing is avoided to prevent the possibility of destructive explosions. In diffusion flames, combustion reactions occur at an interface to which the fuel and oxygen diffuse from bulk sources in accordance with the overall combustion stoichiometry. Thus, there is no unique equivalence ratio that describes a diffusion flame. Although one can define an overall equivalence for a diffusion-flame burner, local equivalence ratio Φ vastly varies from infinity (pure fuel) to 0 (pure air). Because a flame is produced at the stoichiometric interface, the maximum flame temperatures reached in diffusion flames are high, e.g., close to adiabatic flame temperatures.

For stable gas-phase (homogeneous) combustion, flame temperatures generally must exceed 1400 °C, and typically range between ca. 1500 and 1900 °C or more. The high temperatures preheat the incoming fuel and air through conduction, convection, and to a lesser extent by radiation. In premixed systems, the extent of air dilution can be used to control the maximum flame temperature (see Fig. 5). In diffusion flames, however, because stoichiometric conditions prevail at the flame front, the resulting maximum temperatures are considerably higher, e.g., about 2000 °C for natural gas and 2200 °C for diesel fuel flames, respectively. Consequently, diffusion flames are easier to stabilize than premixed flames. On the other hand, the higher temperatures associated with diffusion flames promote the formation of certain pollutants, such as nitrogen oxides and soot.

The pictures of premixed and diffusion methane flames in Figure 6 show that flame luminosity increases with increasing equivalence ratio due to increased production of soot. Increasing luminosity also increases radiative heat transfer, which is desirable to extract as much thermal energy as possible from combustion processes. Also shown in Figure 6 are probes to withdraw samples from within the flames, which subsequently can be analyzed by techniques such as gas chromatography, mass spectrometry, or both. Indeed, these types of measurements have been the primary sources of information on flame chemistry and have contributed significantly to our understanding of the chemistry and mechanisms of combustion. For example, it is now known that flames can contain hundreds of intermediate species. Figure 7 shows concentration profiles of some selected species in a fuel-rich methane flame, such as that shown in the middle picture in Figure 6, as a function of distance along the flame or height above the burner surface.

Figure 6. Laminar premixed flames of methane, slightly fuel rich (Φ = 1, left), fuel-rich and sooting (Φ > 1, center), and diffusion flame (right). Luminosity increases with increasing equivalence ratio.

Figure 7. Concentration profiles of major species (left) and of some of polycyclic aromatic hydrocarbons (PAH, right) formed in a fuel-rich, premixed laminar methane flame. The formation of a large number of intermediates and byproducts is evident [10]. Carcinogenic benzo[a]pyrene is the third PAH from the bottom (right).

Flame Chemistry. As can be seen in Figure 7, even the chemistry of combustion of a simple hydrocarbon fuel such as methane is complex. The fuel molecule, before it ultimately produces CO_2 and H_2O, undergoes a complex series of reaction steps forming a large number of intermediates. The general sequence of reactions that lead to CO_2 production follows:

$$CH_4 \rightarrow CH_3^{\bullet} \rightarrow CH_2O \rightarrow CO \rightarrow CO_2 \tag{3}$$

CO oxidation represents the last sequence in CH_4 combustion, as well as in the combustion of all other hydrocarbons [10]. CO oxidation mainly proceeds by reaction with $OH^{\bullet}$ (Eq. 4).

$$CO + OH^{\bullet} \rightarrow CO_2 \tag{4}$$

$OH^{\bullet}$ is one of the important free radicals in flame-combustion processes, together with $H^{\bullet}$ and $O^{\bullet}$. Collectively $H^{\bullet}$, $O^{\bullet}$, and $OH^{\bullet}$ establish the radical pool in flames through the following chain-branching reactions:

$$H^{\bullet} + O_2 \rightarrow OH^{\bullet} + O^{\bullet} \tag{5}$$

$$O^{\bullet} + H_2 \rightarrow OH^{\bullet} + H^{\bullet} \tag{6}$$

These reactions also constitute the basis for H_2 combustion, an essential submechanism in the combustion of all hydrocarbon fuels. In fact, the destruction of the fuel and the formation and destruction of intermediates are all governed by free-radical reactions. For example, methane in flames is destroyed as a consequence of attack by $H^{\bullet}$, $OH^{\bullet}$, and $O^{\bullet}$ radicals (e.g., Eqs. 7-14).

$$CH_4 + H^\bullet \rightarrow CH_3^\bullet + H_2 \quad (7)$$

$$CH_4 + OH^\bullet \rightarrow CH_3 + H_2O \quad (8)$$

$$CH_4 + O^\bullet \rightarrow CH_3^\bullet + OH^\bullet \quad (9)$$

Once formed, $CH_3^\bullet$ radicals can then undergo recombination and dehydrogenation reactions to form a variety of C_2 species, the concentrations of which can reach substantial levels in fuel-rich flames (see Fig. 7 and Eqs. 10-14).

$$CH_3^\bullet + CH_3^\bullet \rightarrow C_2H_6 \quad (10)$$

$$C_2H_6 + H^\bullet \rightarrow C_2H_5^\bullet + H_2 \quad (11)$$

$$C_2H_5^\bullet \rightarrow C_2H_4 + H^\bullet \quad (12)$$

$$C_2H_4 + H^\bullet \rightarrow C_2H_3^\bullet + H_2 \quad (13)$$

$$C_2H_3^\bullet \rightarrow C_2H_2 + H^\bullet \quad (14)$$

Based on detailed chemical kinetic modeling studies, vinyl radicals appear to play an important role in flame chemistry. In the presence of abundant oxygen, vinyl radicals are rapidly oxidized to CO and CO_2 (Eqs. 15-17).

$$C_2H_3^\bullet + O_2 \rightarrow CHO^\bullet + CH_2O \quad (15)$$

$$CHO^\bullet \rightarrow CO + H^\bullet \quad (16)$$

$$CO + OH^\bullet \rightarrow CO_2 + H^\bullet \quad (17)$$

However, under fuel-rich conditions, further molecular growth becomes likely by competing polymerization reactions that lead to aliphatic C_3 – C_6, aromatic, and polyaromatic species [11] (e.g., Eqs. 18-22).

$$C_2H_3^\bullet + CH_3 \rightarrow C_3H_6^\bullet \rightarrow C_3H_4 + H_2 \quad (18)$$

$$C_2H_3^\bullet + C_2H_2 \rightarrow C_4H_5^\bullet \rightarrow C_4H_2 + H_2 + H^\bullet \quad (19)$$

$$C_4H_5^\bullet + C_2H_2 \rightarrow C_6H_7^\bullet \rightarrow C_6H_6 + H^\bullet \quad (20)$$

$$C_3H_4 + C_3H_3^\bullet \rightarrow C_6H_6 + H^\bullet \quad (21)$$

$$C_6H_6 + C_2H_3^\bullet \rightarrow C_6H_6C_2H_3^\bullet(+C_2H_2) \rightarrow C_{10}H_8 + H_2 + H^\bullet \quad (22)$$

Subsequent reactions of benzene and naphthalene ($C_{10}H_8$) then produce even higher PAHs, examples of which are presented in Figure 7 [11]. The interest in PAH formation and emission arises from the potential toxicity of some of the isomers of PAH. For example, benzo[*a*]pyrene $C_{20}H_{12}$ is an established potent carcinogen in laboratory animals [12]. Further growth of the hydrocarbon byproducts forms species with extremely low vapor pressures. These larger species then condense and undergo dehydrogenation to produce heterogeneous (i.e., liquid) nuclei for soot formation, an important universal characteristic of fuel-rich flames. This sequence of events is shown in Figure 8 [13]. As is evident from the foregoing discussion, the discharge of CO and hydrocarbon intermediates involved in fuel combustion processes can represent the products of incomplete combustion (PIC) emitted from combustion systems.

Figure 8. Schematic of soot growth from fuel molecules via PAH [13]

The combustion chemistry of higher molecular fuels such as propane, butane, gasoline (e.g., heptane, octane) also involves the reactions discussed above. That is, these fuels first undergo decomposition to reactive hydrocarbon intermediates and lower molecular mass fragments, such as methane and ethylene. Thus, it is the combustion of these decomposition products that determines the flame chemistry and PIC emissions from combustion devices burning high molecular fuels. This aspect of combustion chemistry has significantly helped in the development of detailed kinetic mechanisms of combustion of all types of hydrocarbon fuels [10].

Although the nature of intermediates formed in diffusion flames are similar to those in premixed ones, the contact pattern of the fuel and oxidant are significantly different. Figure 9 shows the species concentration profiles across a laminar ethylene diffusion flame front. The fuel arriving on the left and the oxygen on the right diffuse towards each other and undergo virtual annihilation within the flame zone with concomitant establishment of a peak temperature of about 1600 °C, which is

significantly higher than that of a premixed methane flame.

Figure 9. Species concentration profiles versus distance from fuel burner surface for major species (left) and PAHs (right) generated in an opposed-flow ethylene diffusion flame [14].

Similar to premixed flames, a large variety of hydrocarbon intermediates, including PAHs and CO are formed in diffusion flames (Fig. 9). These intermediates are also believed to form by reaction mechanisms similar to those of premixed systems. Since premixed systems provide a better control of combustor performance, and many practical combustion devices operate with separate fuel and air feed conditions, considerable effort has been expended to ensure rapid mixing of fuel and oxygen in combustion chambers and approach premixed conditions. Operation under turbulent-flow conditions is one such approach. In fact, most practical combustion systems today exploit turbulent mixing to dramatically reduce the mixing times of fuel and air.

Although higher flame temperatures are desirable for improved fuel combustion, flame stability, and for increased thermodynamic energy conversion efficiency, there are also drawbacks associated with high flame temperatures. Most significantly, the reaction of atmospheric molecular nitrogen with oxygen to form NO_x increases with increasing temperature, and this creates practical limits on the maximum flame temperatures that can be tolerated in combustion systems. This is clearly illustrated in Figure 10, where equilibrium NO levels are shown to increase with increasing temperature and decreasing fuel equivalence ratio in methane-air mixtures [15]. In flames, molecular nitrogen and oxygen interact with one another in accordance with the following Zeldovich or thermal NO mechanism (Eqs. 23 and 24) [16].

Figure 10. Equilibrium NO concentration as a function of equivalence ratio for various flame temperatures [15].

$$O^{\bullet} + N_2 \rightarrow NO^{\bullet} + N^{\bullet} \tag{23}$$

$$N^{\bullet} + O_2 \rightarrow NO^{\bullet} + O^{\bullet} \tag{24}$$

The kinetics of these reactions are such that their role becomes significant only above 1500 °C. Consequently, diffusion flames are particularly prone to higher levels of thermal NO production because of their higher peak flame temperatures. Besides the Zeldovich mechanism, NO formation can also occur via the prompt NO mechanism [17] and from fuel nitrogen sources. In the promp-NO mechanism, the reactions of CH radicals, produced by sequential degradation of hydrocarbon fuels with N_2, are responsible for NO production (Eqs. 25-30).

$$CH^{\bullet} + N_2 \rightarrow HCN + N^{\bullet} \tag{25}$$

$$HCN + O^{\bullet} \rightarrow NCO^{\bullet} + H^{\bullet} \text{or } NH^{\bullet} + CO \tag{26}$$

$$NCO + H^{\bullet} \rightarrow NH^{\bullet} + CO \tag{27}$$

$$NH^{\bullet} + O^{\bullet} \rightarrow NO + H^{\bullet} \tag{28}$$

$$NH^{\bullet} + H^{\bullet} \rightarrow N^{\bullet} + H_2 \tag{29}$$

$$N^{\bullet} + O_2 \rightarrow NO + O^{\bullet} \tag{30}$$

These and related reactions that are believed to be involved in prompt-NO production are presented in Figure 11 [18]. This reaction mechanism also plays an important role in the thermal deNOx process to remove NO from combustion products by using NH_3.

Figure 11. NO production from fuel reactions [18]

Coals and some heavy petroleum products contain nitrogen bound in organic molecules in amounts ranging from 0.1 to 2.5 % and thereby contribute to formation of nitrogen oxides. The rates of NO_x production from fuel-bound nitrogen strongly depend on combustion conditions, such as the local stoichiometry and temperature. The primary mechanism of NO_x formation in this case is conversion of fuel-bound nitrogen to HCN and HNCO, followed by the conversion of these species to

NH_x and then NO by a reaction mechanism identical to that for prompt-NO described in Figure 11.

In addition to NO, other nitrogen oxides, such as NO_2, and N_2O, can also form in combustion processes. NO_2 is produced from NO in the cooler parts of the combustion chamber (e.g., Eq. 31).

$$NO + HO_2^{\bullet} \rightarrow NO_2 + OH^{\bullet} \quad (31)$$

N_2O can be produced catalytically or by homogeneous recombination (Eq. 32).

$$O^{\bullet} + N_2 \rightarrow N_2O \quad (32)$$

NO_x Abatement. Lowering the amount of NO_x in combustion off-gases is one of the most significant challenges in environmental protection. There are two primary approaches for NO_x control: modifying the combustion process to minimize NO_x production, and postcombustion NO_x abatement. Usually, the nature of the fuel influences the selection of the most suitable approach. For low-nitrogen fuels such as natural gas, thermal NO is the major contributor, and temperature control is the most important parameter. Thus modifications to the combustion process that allow the use of excess air and its rapid mixing with fuel would be most effective to reduce NO emissions. Excess air serves as a diluent which reduces the maximum flame temperature, thereby resulting in lower thermal-NO production. For fuels that contain significant amounts of fuel nitrogen, both the thermal and the fuel NO formation processes become operative. In this case, the most effective strategy is to carry out the combustion process in stages. The first stage operates in a fuel-rich regime, and a second stage is fuel-lean. In the first stage, fuel nitrogen is released primarily as molecular nitrogen as opposed to oxides. In the second stage, unburned hydrocarbons and CO are converted into final combustion products. A variant of the staged-combustion method is reburning [19], [20]. In this case, the fuel – air mixture is first burned with excess air in the first stage, creating substantial levels of NO but relatively little unburned hydrocarbons. The products of the first stage are then introduced into a second stage, where a reburning fuel, preferably natural gas, is also introduced. In the fuel-rich reburning environment, both NO_x formation and removal reactions occur. However, the net effect is a significant reduction in the concentration of NO.

Methods to control NO_x emissions in post-combustion gases can be noncatalytic or catalytic. Noncatalytic methods involve the injection of nitrogen-containing additives at concentrations comparable to those of NO_x into the combustion exhaust gases over a well-defined temperature window to induce NO_x reduction. The additives used and their effective temperature windows are ammonia (NH_3, 825 – 1125 °C) in the thermal DeNOx process [21], cyanuric acid [$(HOCN)_3$, 725 – 1075 °C) in the rapreNOx process [22], and urea [$(NH_2)_2CO$, 725 – 1075°C) in the NOxOUT process [23]. IThe mechanisms responsible for NO reduction in each of these processes are similar. The principal reaction responsible for NO consumption is given in Equation 33.

$$NH_2^{\bullet} + NO \rightarrow N_2 + H_2O \quad (33)$$

A large number of methods have been developed for the selective catalytic reduction (SCR) of NO_x in combustion products [24]. At present, the SCR methods can be categorized into four groups: 1) Direct conversion of NO to N_2 and O_2; 2) SCR of NO with ammonia, primarily for industrial facilities and stationary power plants; 3) SCR of NO with CO and H_2, primarily for automotive applications; and 4) SCR of NO with hydrocarbons, again primarily for automotive applications. Modern auto exhaust emission control technologies largely depend on the utilization of three-way catalysts (TWC) to simultaneously reduce the emissions of CO, hydrocarbons and NO_x [25] (⟶ Automobile Exhaust Control). TWCs primarily utilize 0.1 – 1 wt % precious metals such as Pt/Rh combinations or Pd deposited on a high surface area carrier material primarily composed of γ-Al_2O_3 and CeO_2/ZrO_2 to serve as an oxygen-storage component during transient fuel-rich phases of cyclic engine operation. The γ-Al_2O_3 carrier material is also stabilized by oxides of rare earth and alkaline earth metals such as La and Ba to maintain high surface area and structural integrity under the influence of high temperatures and water vapor associated with engine exhaust gases. New catalyst formulations that can be used in lean-burn gasoline and diesel engines need to be developed to better utilize the higher efficiency of these engines [24].

Sulfur. Coal and some petroleum products also contain sulfur, which forms SO_2 and SO_3 (SO_x) on combustion. Over 60 % of anthropogenic emissions of SO_x are due to coal combustion, 30 % due to petroleum combustion, and the balance due to smelting operations. Anthropogenic emissions contribute over 75 % of the total atmospheric sulfur content, and the sources of these emissions almost exclusively are concentrated in the northern hemisphere. Together, NO_x and SO_x are contributors to acid rain by transformation into HNO_3 and H_2SO_4 in the atmosphere. These emissions, besides their obvious adverse environmental and health effects, also result in the erosion of structural and ornamental stonework and lead to corrosion of equipment. It is generally agreed that SO_2 formation occurs by sequential reactions of sulfur (Eq. 34) [26].

$$\text{Fuel-S} \rightarrow RS \rightarrow SO \rightarrow SO_2 \rightarrow SO_3 \quad (34)$$

The oxidation of SO_2 to SO_3 is thermodynamically favored at lower temperatures. However, since the homogeneous reaction kinetics are slow at low temperatures, SO_2 emissions dominate SO_x emissions from most combustion systems. On the other hand, significant SO_3 formation can occur through heterogeneously catalyzed reaction pathways when the fuel contains transition metals, especially vanadium, which subsequently appear as particulate matter. The most effective way to reduce SO_x emissions is to decrease the use of sulfur-containing fuels. In the absence of this, sulfur oxides can readily be removed from combustion flue gases by adsorption on a sorbent [27]. For example, calcium oxide (CaO), which can be obtained from

abundant limestone, can be used to efficiently remove SO_2 from combustion effluents (Eq. 34).

$$CaO + SO_2 + 1/2O_2 \rightarrow CaSO_4 \quad (35)$$

The $CaSO_4$ formed is stable and thus can safely be stored. However, the management of massive quantities of $CaSO_4$ that accumulate over a period of time can be a problem. Other, regenerative methods of SO_2 removal have also been developed [27].

Combustion of Coal. The combustion of coal is significantly more complicated than with gaseous and liquid fuels due to the presence of inorganic mineral matter (e.g., ash) [41-44]. Nevertheless, coal combustion occurs primarily through the establishment of diffusion flames. In this case, oxygen diffuses towards the solid fuel surface and reacts with either the products of gasification and/or volatilization at the flame zone or with the residual solid carbon. The combustion process can significantly be slowed down by the diffusion barrier created by the mineral matter. Thus, it is necessary to pulverize coal to affect efficient combustion. The solid fuel particles can shrink during combustion, ultimately leaving behind an ash particle. If the resulting ash particles are small, with terminal velocities smaller than the gas velocities, they will be carried over with the hot combustion gases in the form of fly ash. If combustion temperatures exceed the softening temperature of the ash, ash particles can form agglomerates. In any case, ash particles, together with organic particulate matter (i.e., soot) must be removed from the exhaust gases in coal combustors. (See General References on Power Generation)

Incineration is a special category of combustion in which the volume and potential toxicities of hazardous chemical wastes are reduced [8]. Incineration of halogenated hydrocarbons, and in particular chlorinated hydrocarbons (CHCs), have received particular attention since they are present in many consumer and industrial wastes, and their combustion is often associated with the formation of trace byproducts such as chlorinated aromatics, polychlorinated dioxins (PCDD), and furans (PCDF). The combustion stoichiometry of CHCs, designated by the formula $C_xH_yCl_z$, can be described by Equation 35.

$$C_xH_yCl_z + [x + (y - z)/4]O_2 \rightarrow xCO_2 + zHCl + [(y - z)/2]H_2O \quad (35)$$

That is, the thermodynamically preferred combustion product is HCl for $y > z$. However, for CHC compounds in which $y < z$, the formation of molecular chlorine must also be considered (Eq. 36).

$$C_xH_yCl_z + xO_2 \rightarrow xCO_2 + yHCl + [(z - y)/2]Cl_2 \quad (36)$$

Since the formation of Cl_2 is undesirable as it is difficult to scrub from combustion effluents, an auxiliary fuel with sufficient hydrogen content is used to increase the H/Cl ratio and suppress Cl_2 formation.

The combustion kinetics of CHCs also exhibit several distinguishing features when compared to the reactions of analogous unsubstituted hydrocarbons [28]. Most importantly, CHCs decompose easily as a consequence of the weaker C-Cl bond dissociation energies compared to the C—H bond in hydrocarbons, i.e., they start reacting at lower temperatures and begin forming combustion intermediates. Second, chlorine and chlorinated compounds also effectively compete with the important chain-branching combustion reaction of $H^{\bullet}$ radicals $H^{\bullet} + O_2 \longrightarrow OH^{\bullet} + O^{\bullet}$ (e.g., Eqs. 37 and 38).

$$H^{\bullet} + HCl \rightarrow H_2 + Cl \quad (37)$$

$$H^{\bullet} + CH_3Cl \rightarrow CH_3 + HCl \quad (38)$$

Thus, CHCs inhibit hydrocarbon combustion processes. This inhibition manifests itself in the reduction in laminar combustion velocities of hydrocarbon flames and delays in the onset of flame formation. In fact, these features of halogenated hydrocarbons have been exploited to develop effective flame retardants. For example, CCl_4 was used in earlier flame extinguishers, until its adverse health effects were discovered. Subsequently, CF_3Br (halon) was used in fire fighting. However, in spite of its effectiveness, CF_3Br is also banned due to its high ozone-depletion potential. Today, most halogen-based flame suppressants contain hydrogen in their molecules to increase their reactivity and therefore their destruction in the atmosphere by $OH^{\bullet}$ radicals [29].

Combustion of chlorinated compounds is also associated with the potential formation of toxic byproducts such as C_6H_5Cl and chlorinated dioxins and furans (see Fig. 12), as well as PAH and soot. The issue of byproducts in CHC combustion continues to be a highly controversial. This controversy arises from the fact that the 2,3,7,8 isomer of tetrachlorodibenzodioxin (commonly referred to as the TCDD, see Fig. 12) is highly toxic to certain laboratory animals [12]. At present two mechanisms exist to explain the formation of PCDD and PCDF in the combustion of CHC: 1) homogeneous synthesis from aromatic precursors such as chlorinated benzenes and phenols [30], and 2) heterogeneous and/or de novo synthesis from carbonaceous materials with particulate carbon and carbon species with functional groups believed to be the best starting materials [31], [32]. However, with proper design and operating procedures, the formation and emission of dioxins and furans can be minimized, and incineration can effectively be used as a powerful treatment technology in the management of toxic and hazardous wastes.

Figure 12. Formation of tetrachlorodibenzodioxin from 2,4,5-trichlorophenol

From the above discussions, it is clear that intimate mixing of the fuel and air are necessary to achieve clean combustion. However, energy recovery and the need to minimize the formation of NO_x bring additional constraints. For example, operation under fuel-rich conditions, such as those implemented in staged combustion, enhances radiative heat transfer and minimizes thermal NO_x formation. However, fuel-rich conditions promote PAH and soot formation. Thus, practical systems must be designed and operated to achieve the combined objectives of efficient energy recovery and environmental protection.

Modeling Combustion Processes. The objective of combustion modeling is to predict macroscopic phenomena, e.g., the pollutant species concentrations in and emitted from a combustor, from the knowledge of fundamental chemical and physical parameters that are process or device independent, together with a mathematical model for the process [10]. It is now possible and feasible to develop predictive models of combustion processes as a consequence of a number of advances made in related areas. First, with the availability of fast computers together with efficient numerical algorithms to handle stiff differential equations, an increasing complexity of combustion problems can be coded and solved rapidly without making any fundamental assumptions. Second, the quality and quantity of data on the thermochemistry of chemical species and the rates and mechanisms of their reactions relevant to combustion, have improved significantly to such a point that the detailed chemical kinetic mechanisms of combustion can readily be assembled. Third, with advances made in theoretical and computational quantum chemistry, accurate thermochemical information can be obtained via electronic structure calculations.

Some of the fundamental chemical parameters of interest include the thermochemistry of species, e.g., enthalpies of formation, entropies and specific heats, necessary to calculate equilibrium constants, and the reaction rate parameters such as the activation energies (E_a), and pre-exponential coefficients (k_o) for the rate coefficient expression $k_o\exp(-E_a/RT)$ to calculate combustion reaction rates. Relevant fundamental physical parameters of interest include the Lennard-Jones parameters, dipole moments, polarizabilities, and rotational relaxation numbers that are necessary for the calculation of transport parameters such as the viscosity, the thermal conductivity and species diffusion coefficients. These fundamental data, together with their associate uncertainties, are then used in modeling the macroscopic behavior of combustion processes. The Models are also subjected to sensitivity analysis to identify their components that are most important in influencing predictions. Combustion modeling efforts to date has been extremely successful in predicting relevant combustion phenomena in a large number of practical applications, including flames, shock tubes, soot formation, internal combustion engines, detonations [10].

Propellants and explosives also represent a special case of solid combustion, where the combustion reactions are exploited to create an impulse, e.g., to propel a missile or to cause fragmentation and blast [1, 2]. Propellants and explosives can be categorized into two basic groups. In the first category, the fuel and oxidizer parts are separate, such as in case of blackpowder which consists of 75 % potassium nitrate as the oxidizer, with 15 % charcoal and 10 % sulfur as fuels. In the second and more widely used category, the propellant or the explosive molecules combine the properties of fuel and oxidizer. Examples of these monopropellants, include trinitrotoluene (TNT), nitroglycerine (NG), ammonium nitrate (AN), cyclotrimethylene-trinitramine (RDX), and tetramethylene-tetranitramine (HMX). These monopropellants can be used either alone or in various combinations with each other and with other compounds for specific applications. An important aspect of these energetic materials is that, depending on the nature of initial ignition, they can exhibit either deflagrations or detonations. Detonation speeds of RDX and HMX can be as high as 8500 and 9100 m/s, respectively. The mechanisms of combustion of propellants and explosives are quite complex. However, the ultimate combustion products include the thermodynamically most stable compounds, i.e., CO_2, H_2O, N_2, SO_2. When the fuel and oxidant are separate entities, the proximity of fuel and oxidant, i.e., solid particle mixing, is important. In this case, the volatilization and the subsequent transport of at least one of the components would be required to sustain combustion. Volatilization can be achieved through heat transfer from the reaction zone. Consequently, the burning rate depends on gas pressure and particle size. In monopropellants, the mixing of fuel and oxidizer is no longer a problem. In this case, the volatilization and reaction can occur simultaneously. In principle, solid monopropellants, when heated by conduction, undergo surface decompositions and melting. Further heating and volatilization then creates a “fizz” reaction zone, which is followed by the generation of a luminous flame after a brief delay. The burning rates of monopropellants also depend on the pressure. Development of detailed chemical kinetic mechanisms describing the combustion of energetic materials is also being pursued today by a large number of investigators [1, 2].

2.1. Transportation

2.1.1. *Fuels for Transportation*

Transportation can be defined as any process that generates thrust for movement. Other than recently developed fuel-cell and electrically powered vehicles or rockets, all transportation relies on combustion of fossil fuels, primarily petroleum products. Nearly one quarter of total energy in the USA is consumed in the transportation sector, and of that 97 % is accounted for by petroleum products [33]. These fuels, overwhelmingly liquids, comprise gasoline, aviation (jet) fuels, and diesel fuels with only a small percentage being made up of natural gas. The liquid fuels derived from crude oil contain various combinations of different hydrocarbons and can be generally classified by the average molecular weights of the fuels or their carbon number, as shown in Figure 13.

Figure 13. Carbon numbers of various fuels used in the transportation sector

Gasoline (⟶ Automotive Fuels) is a complex mixture of over one hundred hydrocarbons. The hydrocarbons vary by class (paraffins, olefins, naphthenes, and aromatics) and, within each class, by molecular weight. The mixture of hydrocarbons (and added oxygenates, such as methyl *tert*-butyl ether or MTBE) in a gasoline determines its physical properties and combustion performance. Gasoline contains the lightest end of the liquid hydrocarbon fuels and thus is the most volatile, then the aviation fuels are next in terms of molecular weight and are less volatile, and finally there are the diesel fuels which are the least volatile and are considered to be fuel oils. Gasoline is used chiefly as a fuel for internal-combustion engines that

operate in a spark-ignited four-stroke mode. It is produced by the fractional distillation of petroleum; by condensation or adsorption from natural gas; by thermal or catalytic decomposition of petroleum or its fractions; by the hydrogenation of producer coal or gas; or by the polymerization of hydrocarbons of low molecular weight and from CO and H_2 through the Fischer-Tropsch process. The range of temperatures in which gasoline boils is roughly between 38 and 205 °C. There are many different types of gasoline grades from high-octane to reformulated blends to those that contain additives that assist in ignition, complete combustion, and reducing pollutant emissions. The U.S. Clean Air Act Amendments of 1990 required oil companies to make available cleaner gasoline with a higher oxygen content. This higher oxygen content is primarily added in molecules that contain oxygen in order to affect the combustion process to achieve complete oxidation of the gasoline to carbon dioxide and water while trying to eliminate the incomplete byproducts such as carbon monoxide (CO) and unburned hydrocarbons (UHC). Table 2 shows a representative composition of motor gasoline fuel.

Table 2. Sample composition of gasoline

Compound	Weight %
C_4	5
C_5	12
C_6 (nonaromatic)	15
C_7 (nonaromatic)	10
C_8 (nonaromatic)	5
C_9 (nonaromatic)	3.2
C_{10} (nonaromatic)	6.1
Benzene	3.2
Toluene	16
Xylenes	12
Styrene	0.7
C_9 aromatics	8
Other minor components	5.9

Aviation fuels (⟶ Aviation Turbine Fuels) are a subset of the fuel oil or diesel category and are comprised of a very narrow range of hydrocarbon types. These fuels conform to specific guidelines that control the ability of the fuel to flow at extreme temperatures as well as its ignition characteristics. The lower freezing point jet fuels are particularly suitable for long international flights, especially over polar routes during the winter. An aviation jet fuel's carbon number range is restricted by distillation, freezing point, and sometimes amount of naphthenes and/or smoke point requirements for the product. Kerosene-type jet fuel has a carbon number distribution between about 8 and 16; wide-cut jet fuel, between about 5 and 15 carbon numbers. Most of the hydrocarbons in jet fuel are members of the paraffin, naphthalene, or aromatic classes. When jet fuels of the same type differ, it is because they contain different proportions of compounds from these three classes.

Diesel fuels (⟶ Automotive Fuels) are also classified on the basis of various properties such as boiling point, freezing point, pour and cloud point, cetane number, density, viscosity and heating value. The reason for the existence of more specifications for the diesel fuels is their broader use in transportation, aviation, residential, and commercial purposes. A typical carbon number distribution for no. 2, diesel fuel, which is the dominant transportation fuel is shown in Figure 14. As with the other liquid fuels, diesel is a complex mixture of hundreds of individual compounds, most with carbon numbers between 10 and 22. Additives are also incorporated into diesel fuels to assist in ignition and combustion performance, and to visually distinguish various grades.

Environmental regulations have had a significant effect on the formulation of diesel fuels. The introduction of new fuels, coupled with the rapid changes in engine design to meet new emission regulations, has created the need to address several fuel properties to ensure proper performance, while also minimizing engine maintenance problems. The fuel with these enhancements is often called premium diesel, although other names are also used. The premium diesel concept is not the same as that of premium gasoline. Gasoline engines of certain types and compression ratios require a higher octane fuel to avoid knocking. Therefore, premium gasoline is required for these vehicles and is provided by all fuel suppliers. Premium diesel, on the other hand, is related to varying one or more fuel properties. Some of the these properties are cetane number, low-temperature operability, stability, lubricity, detergency, and heating value. Figure 14 shows the relative differences and classifications and cuts of gasoline, diesel, and aviation fuels with regard to carbon number distribution.

Figure 14. Typical distribution of carbon-containing compounds in no. 2 diesel fuel

2.1.2. *Combustion in the Transportation Sector*

Internal combustion (IC) engines are the primary combustion technology used in the transportation sector. They have many

uses: transport vehicles (motorcycles, automobiles, trains, aircraft, boats/ships); electric generators; pumps, gas compressors; construction equipment, agriculture and gardening equipment (mowers, chain and rotary saws, blowers). There are three major different types of IC engines employed today. The first is the spark-ignited (SI) four-stroke gasoline or Otto cycle engine, named after the inventor Nikolaus August Otto, which most passenger automobiles employ, in which combustion is best approximated by a premixed turbulent flame. The second type is the diesel engine, named after Christian Karl Diesel, which operates with direct injection, compression ignition (DICI) where the combustion process is very similar to a turbulent diffusion flame. Diesel engines are employed in trucks, buses, trains and in some automobiles, as well as in electricity-generating and marine-power plants. Both Otto-cycle and diesel engines are manufactured in two-stroke and four-stroke models. The third type is the rotary or turbine engine where combustion occurs in a chamber or “can”, where the combustion can be in the form of turbulent premixed or diffusion flame, depending on the application and fuel used.

The Gasoline Engine. In the four-stroke engine, first the intake valve opens and the piston moves down, creating a vacuum, and a mixture of air and vaporized fuel (gasoline) is drawn into the cylinder through the intake valve port (Fig. 15). When the piston reaches the lower limit of its travel, it begins to move upward. As this happens, the intake valve closes, as does the exhaust valve, sealing the cylinder. As the piston moves upward, the air-fuel mixture is compressed. In some small, high-compression engines, by the time the piston reaches the top of its travel, the mixture is compressed to as little as one-tenth of its original volume. Thus, the compression of the air-fuel mixture increases the pressure in the cylinder. The compression process also raises the temperature of the air-fuel mixture by adiabatic compression, yet the temperature is not high enough to ignite the mixture. As the piston reaches the top of its travel on the compression stroke, an electric spark is produced by the spark plug, which ignites the air-fuel mixture. The mixture burns rapidly, and cylinder pressure increases to as much as 4 MPa in a very short time and forces the piston down in the cylinder. The power impulse is transmitted down through the piston, through the piston rod (connecting rod), and to the crankshaft, which rotates. As the piston reaches the bottom of its travel, the exhaust valve opens. Now, as the piston moves up on the exhaust stroke, it forces the burned gases out of the cylinder through the exhaust port. When the piston reaches the top of its travel, the exhaust valve closes, and the intake valve opens. The cycle repeats again with the intake stroke. The four strokes are continuously repeated during the operation of the engine.

Figure 15. Spark-ignited gasoline engine [1]

During combustion there is a volumetric expansion of gases due to the greater number of moles of products than reactants. This is one of means of providing force on the piston to turn the drive shaft. Another means of creating a volume expansion is by the temperature rise caused by the change in enthalpy from reactants to products, i.e., the heat of combustion. Because the heat of combustion cannot be completely converted to mechanical energy, all engines must be equipped with some type of cooling system. Some aircraft and automobile engines, small stationary engines, motorcycles, and outboard motors for boats are cooled by air. In this system the outside surfaces of the cylinders are designed in an array of fins to expedite the dissipation of heat. Other engines are liquid-cooled and have their cylinders enclosed in an external liquid jacket. In automobiles, the coolant is circulated through the jacket by means of a liquid pump and the heated coolant subsequently is cooled by passing through the finned coils of a radiator.

As noted above, the power stroke is when the combustion energy is released. Since it is desirable to rapidly release of the chemical energy stored in the fuel, to prevent engine knock, significant effort has been spent to design fuel-delivery systems to generate highly premixed conditions. The premixing allows the flame front to progress rapidly through the mixture at a flame velocity determined by the equivalence ratio and the temperature attained during the compression process, with the maximum flame velocity attained under stoichiometric conditions. Interestingly, all present day SI engines operate nearly at stoichiometric conditions. However, there is a growing interest to operate internal combustion engines with excess air to improve fuel economy [25].

While there are many parameters that effect the final outcome of the combustion process, such as cold surfaces, level of unmixedness, turbulence, and pressure variations, an understanding of premixed flame combustion processes (see Chapter 2) have led to significant improvements in SI engine design and operation. For example, the combination of chemical kinetic mechanisms of combustion, determined from well-defined studies on premixed flames, with fluid dynamic models that represent the piston-cylinder systems have provided crucial insights into the origins of pollutants that are emitted from SI engines, leading to improved cylinder and piston-ring designs [10]. The majority of emissions caused by gasoline SI combustion systems are CO, NO_x, and UHC, which are greatly reduced by three-way catalytic converters [25].

The Diesel Engine. The four cycles of the gasoline engine are not much different in the diesel engine. However, in the diesel engine the fuel is not mixed with the air entering the cylinder during the intake stroke. Instead, the air alone is compressed during the compression stroke, and the diesel fuel is injected or sprayed into the cylinder at the end of the air-compression stroke. Compression ratios can be as high as 25:1 and generate pressures of to 3.5 MPa and temperatures as high as 550 °C. This temperature is high enough to spontaneously ignite the fuel as it is injected into the cylinder. The high pressure of the explosion forces the piston down, as in the case of gasoline engine. Since the fuel is injected as a liquid into the cylinder and forms droplets, the combustion occurs primarily through a diffusion-flame process in diesel engines. There are a number of complicating issues in diesel engines that are not present in SI engines. First, there is a need to sequentially vaporize, mix, and burn the liquid fuel with air within the time period of a compression/expansion stroke. If this is not achieved, products of incomplete combustion are emitted from the engines. In fact, diesel engines are well known for their significantly higher CO, hydrocarbon, PAH, and soot emissions when compared to gasoline engines. Second, because of the presence of diffusion

flames, diesel engines also exhibit higher local flame temperatures and thus generate higher levels of thermal NO_x.

Jet Engine. Jet engines, which exploit combustion-generated thrust, are associated with all modern aircraft. Jet engines enable the rapid transportation of large masses of people inexpensively over long distances. The gas turbine engine is widely used in both civilian and military sectors. However, regardless of the field of application, the main components of jet engine are similar (Fig. 16). The jet engine uses air as the working fluid to provide thrust. To achieve this, a compressor is used to increase the pressure and temperature of the inlet air to about 200 – 550 °C. Fuel, such as jet fuel or kerosene, is then sprayed into the pressurized air and ignited. Heated air and combustion products then pass through a turbine, which converts some of the combustion energy released into rotational energy to drive the compressor. The hot gases are then expanded through a nozzle producing high-velocity jet exhaust, which is used to propel the aircraft. The amount of fuel added to the compressed air depends on the temperature rise needed. However, the thermal properties of the turbine blades and other engine parts generally determine the maximum temperature that can be tolerated, which is in the range 850 – 1700 °C. Modifications of the gas-turbine engines include the use of multiple chambers and burners.

Figure 16. Schematic of a gas-turbine engine [1]

2.1.3. *Emissions from Combustion in the Transportation Sector.*

UHC, CO, and NO_x. Gasoline-powered vehicles tend to be the greatest emitters of CO, and substantial emitters of UHCs and NO_x, but only modest emitters of PAH and particulate matter (PM), while diesel-powered vehicles are substantial emitters of PAH, PM, and NO_x, as well as CO and UHCs.

UHC and CO emissions are incomplete combustion products that arise primarily because of lack of mixing of the fuel and air, i.e., innappropriate equivalence ratio. Secondary reasons for the emissions of these pollutants from combustion systems include the short residence times and lower local temperatures. According to the estimates by the EPA, gasoline engines are responsible for almost 75 % of anthropogenic CO emissions. One explanation of this is the difficulty in controlling emissions in periodically operated IC engines, where transient conditions are the norm. In contrast, stationary combustion facilities that operate continuously under nearly steady-state conditions are easier to control. The EPA estimates also indicate that gasoline engines generate about 24 % of the anthropogenic NO_x emissions. As discussed in the Introduction, CO and UHC are the primary products of incomplete combustion of fuel, and the main factor influencing their formation is the equivalence ratio. Stoichiometric mixtures are generally desirable to minimize UHC. On the other hand, NO_x production is primarily determined by reaction temperature, and thus stoichiometric conditions increase its production (Fig. 5). Therefore, a proper engine design involves a careful balance that simultaneously minimizes CO and NO_x emissions while maintaining stable operation.

PAH are generated in trace quantities as incomplete combustion products by all internal combustion engines. Mobile sources such as internal combustion engines burning gasoline and diesel fuel have been implicated as major contributors to PAH emissions in urban areas [34]. Quantitative data has been generally lacking for PAH emissions from aircraft, ships, heavy machinery, and two-stroke engines such as motorcycles, outboard motor powered boats, and lawnmowers. For example, vehicles using unleaded gasoline produce about 173 µg/km of naphthalene and 1.4 µg/km of pyrene [35]. However, because of their accumulation, even trace amounts emitted can pose a risk to human health and the environment over a period of time. Different PAH are also partitioned and react differently in the environment. For example, the phase distribution for naphthalene has been estimated to be 73 % in air, 8.5 % in water, and 17 % in soil, whereas the distribution of pyrene is 99 % in soil, 0.72 % in water, and 0.13 % in air. Significant PAH is also known to be associated with particulate matter emitted from combustion sources. Some PAH undergo atmospheric reactions and form products that are even more toxic than the parent molecules. For example, the formation of nitroaromatics (some of which are potent carcinogens) has been demonstrated for atmospheric reactions involving ozone and NO_x [36]. Clearly, the most effective strategy to protect the environment and human health from PAH is to minimize their emission from combustion devices in the first place. This indeed is the focus of intense research and development in combustion science and technology.

To avoid the emission of PAH from combustion devices, the use of gaseous fuels such as natural gas is expected to increase in the future. Because of the ease of premixing gaseous fuels with air prior to flame formation, combustion reactions proceed under conditions where the local equivalence ratio never reaches the sooting limits. Methane is the largest constituent of natural gas, present at concentrations of 85 % and above, followed by ethane at 10 % and below, then propane at 3 % and below. Smaller concentrations of butane and inert substances, such as carbon dioxide, nitrogen, and water are also present in natural gas. This mix gives natural gas an average hydrogen to carbon ratio (H/C) of about 3.5, which is considerably higher than those of petroleum-derived liquid fuels or coal. The use of natural gas as a combustion fuel is also desirable from the global warming point of view. First, because of its high hydrogen to carbon ratio, natural gas produces more water vapor and less carbon dioxide than liquid fuels or coal with the equivalent heat of combustion. Second, the combustion of methane is preferable to its direct venting to the atmosphere, which often is done at oil wells and remote gas wells, as methane is a more potent greenhouse gas than carbon dioxide.

Liquid fuels are generally expected to generate higher quantities of PAH than gaseous fuels due to their constitution. For example, gasoline and diesel fuels contain significant concentrations of aromatics and PAH, such as benzene and naphthalene, which serve as initial templates for further polymerization to form even larger PAH. Gaseous fuels, on the other hand, do not have such intrinsic templates, and as such are expected to produce less PAH than liquid fuels. Among the gaseous fuels, a similar trend is also observed. That is, the propensity for PAH formation increases with increasing molecular weight and decreasing H/C ratio. However, methane has been noted to be an exception. In a study with premixed flames,

higher concentrations of in-flame gas-phase aromatics and PAH were noted to exist in methane flames than in ethane flames [37], although soot formation was higher in the latter. This surprising finding was attributed to the presence of a larger set of reactions leading to PAH formation in the methane flame, as well as to the adsorptive removal of PAH from the gas phase in the sootier ethane flame.

Particulates. Particulate matter (PM) is solid or liquid particles in air that are larger than single molecules (ca. 0.0002 µm in diameter) but smaller than 500 µm. Combustion-generated PM is mostly soot. PM can be directly emitted from combustion systems or formed in the atmosphere through a series of chemical and physical events. Some PM is large or dark enough to be seen as soot or smoke, but mostly an electron microscope is necessary to detect it. Because PM originate from a variety of mobile and stationary sources (diesel trucks, woodstoves, power plants, etc.), its chemical composition and physical properties can vary. PM has lifetimes in suspension in air that vary from a few seconds (large particles) to several months (submicron particles). Particles less than 0.1 µm in diameter undergo random Brownian motion resulting from collision with individual molecules and can remain suspended in air indefinitely. Particles between 0.1 and 2 µm in diameter have small settling velocities in still air, and thus can be transported with prevailing winds. These particles tend to be removed by rain or washout. Particles larger than 2 µm have significant but small settling velocities. Particles above 20 µm in diameter have larger settling velocities and are removed from the air by gravity and other inertial processes, such as impaction. Since Brownian motion influences smaller particles, and inertial forces the larger ones, there is usually a stratification of the type of PM with distance from a given source. For example, PM emitted from a moving truck or car would deposit most of the largest particles on the roads or right-of-way, whereas the smaller particles would be carried significantly further throughout the environment and are more likely to be ingested.

Particulate emissions from all engines are of increasing concern due to growing awareness of their impact on human health. The chemical and physical characteristics of engine PM emissions depend on fuel composition, the engine design, whether it is carbureted or fuel-injected, and the cycle, two- or four-stroke. With leaded gasolines used earlier, lead compounds dominated the particulate emissions. With unleaded fuels, the PM comprise primarily soot particles. In addition, inorganic compounds such as ash, rust, and sulfates (from sulfur present in the fuel) can also form as PM. In the common four-stroke gasoline engines, PM emissions are typically on the order of 1 µm. The particles largely are formed and grow in the exhaust system by vapor-phase condensation. Soot forms in fuel-rich environments in flames when the fuel molecules are first pyrolyzed, then polymerize and condense into PM.

Diesel PM consists mostly of carbonaceous material generated from pyrolysis, incomplete combustion, or both. In addition, diesel fuel has a very high content of aromatics and is typically injected into the combustion cylinder as a liquid. The liquid is sprayed through a nozzle that generates a fine mist to assist in vaporization. This mist consists of many tiny liquid particles and must penetrate the combustion cylinder. The fuel-injection system parameters that determine the fuel injection rate, droplet size distribution and penetration into the combustion chamber, fuel vaporization, fuel – air mixing, and air temperature strongly influence the properties of the PM formed in diesel engines. Over 90 % of the particles released from two stroke diesel engines are less than 0.1 µm in size [38]. Similar to the gasoline engines, the formation of the particulates occurs via agglomeration of and surface deposition on very small particles originating from hydrocarbons in the diesel fuel. There is some evidence that the soot and PM emissions from combustion processes can have an impact on climate change [39].

As discussed earlier, methods are being developed to reduce the amount of pollutants that are emitted from combustion devices. Widely successful catalytic converters are one example of such a technology. Similarly the use of oxygenated fuel additives (e.g., MTBE) and oxygenated fuels (e.g., ethanol) provide benefits in decreasing pollutant emissions from combustion devices. These technologies, together with improvements in engine design and operation, have helped and will continue to help reduce the emissions of pollutants into the atmosphere. Of course, a variety of new technologies are also emerging that will dramatically reduce pollutant emissions from the transportation sector. Examples of these technologies include the hybrid gasoline/electric and the gasoline/hydrogen fuel cell vehicles, and ultimately the totally electric vehicle.

2.2. Power Generation

2.2.1. *Fuels for Power Generation*

Fossil fuels account for more than 70 % of power generated, of which coal has a contribution of 56 %, followed by natural gas with 10 %, and liquid petroleum products with 3 %. Nuclear plants provide about 20 % and hydroelectric sources about 10 % of our electricity demand. In spite of larger coal reserves, which are expected to last for several hundred years, there is a push towards increased use of natural gas combustion in power generation today because of increasing concerns over excessive CO_2 emissions and their potential impact on global warming. The resistance to nuclear power and the abundance of coal and natural gas reserves ensure their use for probably the next 100 years. Based on projections until 2020 (see Fig. 2), coal is expected continue to be the dominant fuel but to provide only about 42 % of electricity needs, followed by natural gas at 30 % [40]. The same study also predicts that nuclear plants will contribute about 10 % of our electricity demand, with the remaining 18 % coming from oil and hydro and other renewable resources. Since the combustion of liquid and gaseous fuels are discussed in Section Transportation, the focus of this section is on coal combustion.

Coal (⟶ Coal) is a solid, black carbonaceous material that comprises many different compounds in varying amounts. The composition varies significantly with source (mine), and even differs from location to location at the same source. While there is a significant variation in composition, the typical make up can be considered as follows: 60 – 95 % carbon, 2 – 7 % hydrogen, 1 – 30 % oxygen, usually about 0.5 – 10 % sulfur, and 0.25 – 2 % nitrogen. In addition, inorganic material such as aluminum, silicon, iron, thorium, uranium, and titanium typically exist in coal in amounts of 5 – 15 % and become ash when coal is combusted. The ash consists of inorganic oxides, such as silicon dioxide (SiO_2) or aluminum oxide (Al_2O_3) and consequently possesses a high melting temperature and therefore can form an outer layer or shell around the coal particle as it is burning. This presents special problems in that the layer is, at the very least, a resistance to diffusion of oxygen to reach the fresh fuel or for the products to diffuse away. The ash layer that forms may significantly arrest the combustion process, therefore leaving a large amount of the energy in the coal particle unused. A considerable amount of water is often incorporated in coal, usually in the range 2 – 20 %. This wide variation in composition makes it very difficulty to accurately predict the combustion characteristics of this fuel. Nevertheless, the combustion of coal can be considered as diffusion-flame-like, with the added complication of the ash layer. Table 3 lists compositions of some typical ranks of coals, together

with their energy content. Lignite is the lowest rank of coal with high contents of moisture and volatile matter and low heating value, especially on wet basis. Bituminous and subbituminous coals are next in rank, with lower contents of moisture and volatile matter and higher carbon content and heating value. Anthracite, the most metamorphosed coal, has low moisture and the highest carbon content. An excellent source of information on the classification, characterization, processing, and use of coals is *Chemistry of Coal Utilization* [41].

Table 3. Proximate and elemental analysis of some coal ranks, in wt % [42]

Type	Moisture	Fixed carbon	Volatile matter	C	H	N	S	O	Ash	Dry Heating Value, kJ/g
Anthracite	4.3	81.0	5.1	79.7	2.9	0.9	0.8	6.1	9.6	34 940
Bituminous	2.1	67.4	24.4	81.6	5.0	1.4	1.0	4.9	6.1	35 910
Lignite	15.2	43.1	40.7	70.1	5.1	1.1	1.6	21.4	5.9	28 280

2.2.2. *Combustion in the Power-Generation Sector*

Coal combustion is a complicated process which is not adequately understood [43-45]. However, it involves essentially two sequential steps: coal volatilization followed by char oxidation. When coal is subjected to high temperatures, it softens, and water is evaporated first. This is followed by the release of volatile organic material consisting of gases and tarry substances. The remaining mass, depleted in oxygen and hydrogen, and enriched in carbon, nitrogen, sulfur and mineral matter, is referred to as char. Volatilization products react with oxygen in the vicinity of the coal particle in a diffusion-flame mode, and this further heats the char. The char particles have cracks and holes made by escaping gases, can swell to a larger size, and thus can be considerably porous. Char combustion is believed to be a heterogeneous reaction process in which oxygen diffuses through the growing ash layer, is adsorbed on the char, and reacts to form carbon oxides, which diffuse back into the bulk gas stream. This heterogeneous process is much slower than the devolatilization step and thus limits the completion of coal combustion. In addition, this time scale is proportional to the original size of the coal particle. Consequently, all modern coal-combustion facilities utilize powders as opposed to granules or lumps of coal. Any residual mass that is not fully oxidized or cannot be transferred into the gaseous state or both (e.g., Al_2O_3, TiO_2, or C) can act as a seed particle to encourage further agglomeration or growth and becomes fly ash or slag. That is why coal combustion is very susceptible to particulate matter emissions, either carbon-based or inorganic.

Char combustion can occur in three distinct operational regimes. At low temperatures, the diffusion of oxygen to the surface is very fast compared to the rate of surface reaction, thus intrinsic reaction kinetics (R_{rxn}) limits the rate of combustion. The rate expression for R_{rxn}, can be given by Equation 39.

The rate expression for R_{rxn}, can be given by Equation 39.

$$R_{rxn} \approx S\rho d[O_2]^n A e^{-E/RT} \tag{39}$$

Where S is the surface area, ρ the density of the char, d the diameter of the char particle, $[O_2]$ the oxygen concentration of the bulk gas, n the order of the surface reaction, A and E are the Arrhenius parameters of the surface reaction, and T is the temperature. At high temperatures, surface reaction rates become very high, so much so that the rate of diffusion R_{diff} of oxygen to the char surface becomes the limiting process for combustion. Under these external diffusion limited conditions the oxygen reacts as soon as it reaches the char surface. The combustion reaction rate expression is then given by Equation 40.

$$R_{diff} \approx \left(\frac{D_o}{d}\right)\rho_o\left(\frac{T}{T_o}\right)^{0.75} \ln F \tag{40}$$

Where D_o is the average bulk gas diffusion coefficient, d is the characteristic char particle diameter, T is the reaction temperature, ρ_o and T_o are the reference gas density and temperature, and F is a function of the oxygen mass fraction in the bulk gas far from the particle (i.e., inlet O_2 concentration). From Equation 37, it can be seen that the combustion rate is inversely proportional to the particle diameter and moderately dependent on the temperature. Lastly, since the process is diffusion-controlled, the reaction rate is independent of the coal composition. In some applications, combustion can proceed at intermediate temperatures, so that observed combustion rates will be between R_{rxn}, and R_{diff}. Under these conditions, the oxygen is transported rapidly to the external surface of the char, but diffuses relatively slowly through the pores.

The amount of heat generated in coal combustion is related to its composition or rank. Carbon, the major component of coal, is the principal source of heat, generating about 32 000 kJ/kg at full combustion. Although hydrogen combustion can generate about 136 000 kJ/kg of heat, its presence in coal as fuel is limited to less than 5 – 6 %. Consequently, the heat of combustion of anthracite is closer to that of pure carbon (see Table 4). On the other hand, higher the oxygen content of coal, the lower its heating value. This is due the fact that oxygen in coal is chemically bound to the carbon, which is therefore already partially oxidized. The amount of heat contributed by the combustion of sulfur in coal is also relatively small, because of its low concentration in coal and low heating value.

Table 4. The role of combustion in the industrial sector in the USA (% total energy from

Industry	Steam	Heat	Combustion

Petroleum Refining	29.6	62.6	92.2
Forest Products	84.4	6.0	90.4
Steel	22.6	67.0	89.6
Chemicals	49.9	32.7	82.6

Most of the power-generation facilities in the USA today utilize fluidized-bed combustors (FBC), which not only allow the efficient operation of the combustion and associated heat-transfer processes, but also enable the control of pollutant emissions without external emission control devices (e.g., gas scrubbers). Fluidized beds suspend solid fuels on upward-blowing jets of air during the combustion process, as shown in Figure 17. The result is a turbulent mixing of gas and solids, and the heat-transfer tubes embedded into the bed allow the generation of steam. Cyclone separators are used to remove particulate matter from the flue gas prior to its entry into a gas turbine. The latter can be designed to accept a moderate amount of particulate matter, or ruggedized. The tumbling action, much like a bubbling fluid, provides more effective chemical reactions and heat transfer. In fluidized beds, coal burns at temperatures of 750 to 950 °C, well below the threshold for formation of nitrogen oxides (ca. 1400 °C). The mixing action provided by the fluidized bed also brings the flue gases into intimate contact with a sulfur-absorbing chemicals, such as limestone or dolomite, thereby removing more than 95 percent of the sulfur pollutants inside the reactor. Pressurized fluidized-bed combustion (PFBC) is a newer technology, and builds upon the earlier work in atmospheric fluidized-bed combustion technology. Power plants utilizing PFBC are significantly smaller and more efficient.

Figure 17. Schematic of an atmospheric-pressure fluidized-bed coal-fired boiler [17]

Another important reason for the popularity of fluidized-bed combustion technology is its fuel flexibility. Almost any solid fuel can efficiently be burned in fluidized-bed combustors, from low-rank lignites to anthracites. Even municipal waste can be burned as fuel in FBCs. This fuel flexibility, as well as the ability to meet sulfur dioxide and nitrogen oxide emission standards without the need for expensive add-on measures, has made FBC as the technology of choice in the power generation industry.

The majority of coal-fired power plants use steam turbines to produce electricity. However, as natural gas becomes more prevalent, the gas turbine engine will be used more for power generation. Currently, the primary fuel for gas turbines is natural gas, which is combusted in a premixed-flame mode. Some turbine combustors have small natural-gas diffusion flames as pilots to ensure the main premixed flame is stable. Other, usually older, designs employ a diffusion-flame combustor. These flames are described in Chapter Conventional Combustion. Natural gas is increasingly becoming the fuel of choice for new electricity projects worldwide. Improvements in gas turbine technology, the fact that natural gas burns cleaner than other fossil fuels, and confidence in its availability are factors that favor power generation using natural gas fueled generators. In fact, natural gas is currently (ca. 2002) the fuel for about 90 % of proposed new generation in the USA and is expected to gain shares relative to coal and nuclear power. Gas consumption is also expected to grow in South America, Asia, and the Middle East. Western Europe is moving away from reliance on nuclear power in favor of natural gas, and Eastern Europe is also expected to expand its natural gas capacity and depend less on coal. Unless rising natural gas prices stifle the forecast growth, world consumption of natural gas as a fuel will grow from 16 % in 1996 to 25 % in 2020 [46], mostly at the expense of coal (Fig. 2).

2.2.3. *Emissions in the Power-Generation Sector*

While NO_x emissions are on par with the transportation sector, coal-fired power plants also emit significant amount of radioactive material and sulfur oxides. Coal ash is composed primarily of oxides of silicon, aluminum, iron, calcium, magnesium, titanium, sodium, potassium, arsenic, mercury, and sulfur plus small quantities of uranium and thorium. Fly ash is primarily composed of noncombustible silicon compounds (glass) melted during combustion. Small glass spheres form the bulk of the fly ash. Trace quantities of uranium in coal range from less than 1 ppm in some samples to around 10 ppm in others. Generally, the amount of thorium contained in coal is about 2.5 times greater than the amount of uranium. For a large number of coal samples, according to EPA figures released in 1984, average uranium and thorium contents were determined to be 1.3 and 3.2 ppm, respectively. Using these values along with reported and projected consumption of coal by utilities provides a means of determining the amounts of potentially radioactive elements emitted by coal combustion. The main sources of radiation released from coal combustion include not only uranium and thorium but also their daughter products produced by the decay of these isotopes, such as radium, radon, polonium, bismuth, and lead. Although not a decay product, naturally occurring radioactive ^{40}K is also a significant contributor.

Electric power generation contributes nearly 50 % of all nitric oxide emissions, with the transportation sector accounting for the remaining 50 %. The electric utility sector is also the major source of sulfur oxides SO_x because of the dominant role of coal in power generation. Over the next decade, power plant operators will face significant requirements to reduce emissions of SO_2, NO_x, CO_2, and Hg. At present, neither the future reduction requirements nor the complete timetable is known for any

of these airborne emissions, and compliance planning is difficult. However, in response to the U.S. Clean Air Act Amendments of 1990 (CAA90), power plant operators are now reducing emissions of SO_x and NO_x.

The SO_x emissions can be controlled by the use of low-sulfur coal or other fuels such as natural gas and diesel that do not have sulfur to start with or can be processed to remove sulfur by passing it through sorbent beds. However, NO_x is still a problem because it comes from the nitrogen in the air and from the significant nitrogen concentrations in the coal matrix. A major effort therefore is focused on NO_x reduction. Those techniques vary from aftertreatment processes which prevent NO_x formed in the combustor from escaping into the exhaust to preventing the formation of NO_x in the first place. Some important NO_x abatement technologies are discussed in Chapter 1.

Techniques to prevent NO_x formation include lean premixed combustion, staged combustion, stoichiometric combustion with water injection, exhaust gas recirculation, and catalytic combustion. While significant progress has been made, with the exception of catalytic combustion, there is still reluctance to adopt these NO_x prevention techniques because of the possibility of destabilizing the combustion process.

2.3. Industrial, Commercial, and Residential Combustion

2.3.1. *Fuels for Industrial, Commercial, and Residential Use*

Combustion is universally used in the industrial, commercial, and residential sectors to meet steam and heat requirements. In addition to the basic premixed and diffusion-flame combustion modes, the combustion devices used in these sectors can be categorized into confined (indirect) and unconfined (direct) types. In the confined or standard “can” combustors, the combustion process is kept in a separate chamber remote from the point of application, such as in heaters, steam generators and boilers, where the products of combustion are exhausted. In other applications, the combustion process remains directly in contact with the application, as is the case with incinerators, some kilns, some space heaters, driers, and cooking stoves.

The fuels used in these sectors are predominantly gas (natural gas or refinery fuel gas) to about 70 – 80 % and to a lesser degree liquid petroleum products, such as diesel fuel, at 20 – 30 %. Residential applications also include fireplaces as space heating devices, and thus wood can also be considered as a fuel for this sector. Coal, once important to residential and commercial consumers, has almost totally been replaced by natural gas in most industrialized countries.

2.3.2. *Combustion in the Industrial, Commercial, and Residential Sectors*

Industry heavily relies on combustion for the production of a diverse array of products (Table 4). For example, boilers, furnaces and other process heaters consume roughly two-thirds of the total energy used by the manufacturing industries. Boilers are used in every major industry, and natural gas is the most common fuel. Exceptions are the petroleum and paper industries, where waste materials such as the refinery fuel gas and wood and pulp are available as fuels. Two primary boiler types are used in industry: water tube and firetube. In the former, tubes carrying water and steam are exposed to the products of combustion. In the firetube boilers, the products of combustion are carried inside the tubes, which heat the water and steam passing over them in the boiler vessel. Fluidized beds are also used in steam generation. In this case a fuel is burned inside a bed of granulated particles (sand) which are suspended by the upward flow of air and combustion products. Tubes carrying water are located inside the fluidized bed of particles.

Process heating equipment include furnaces, ovens, reactors, kilns, incinerators and dryers. Process heaters operate at low to medium temperatures, while furnaces, incinerators, and kilns operate at higher temperatures. The largest number of furnaces are found in the metals, metals fabricating, and heat-treating industries, followed by the glass and cement industries. The variety of process heating functions include changing the properties of materials, such as oxidation, reduction, decomposition, curing, baking, and drying. The nature of the material and the desired change determine the process temperature and the composition of the atmosphere employed in furnaces. Furnaces can be directly or indirectly fired. In directly fired furnaces, the flame and combustion products contact the material being processed. Examples of these types of applications include cement manufacturing and waste incineration. In indirectly fired furnaces, the combustion zone is confined to a separate chamber to prevent the contact of combustion products with the charge.

Commercial and residential applications of combustion are space heating, water heating, cooling, and cooking. Most commercial and residential combustion systems are designed for and operate at much less than optimal efficiencies to facilitate reliability and ease of use by inexperienced operators, and for esthetic reasons.

2.3.3. *Emissions in the Industrial, Commercial, and Residential Sector*

Pollutant emissions from these sectors are highly variable and sector-specific. Commercial and residential sectors, burning predominantly gaseous and liquid fuels, can produce the typical hydrocarbon-combustion emissions that include CO, NO_x, SO_x, particulates, and polycyclic aromatic hydrocarbons (PAH). Historically, residential wood combustion contributed the largest quantity of CO and VOC emissions in the stationary-source sector. However, with the switch to gaseous fuels, the control of trace levels of pollutants now dominate the development of new technology. The industrial sector contributed about 10 % of total U.S. NO_x emissions in 1998, the residential and commercial sectors approximately 5 %, the balance coming from the transportation and power-generation sectors.

Stationary sources such as residential heating that employ fireplaces and coal or diesel furnaces, meat cooking operations, open burning, coal-fired power plants, and coke ovens are other contributors to PAH emissions.

Relatively large peak exposures of PAH can be expected in local environments when charcoal grilling of meat products occurs. Although the grilling of meat is not likely to contribute a major fraction of the total PAH emissions to the atmospheric environment, studies have shown that local PAH levels are approximately 1000 times higher when charcoal grilling of meats occurs relative to PAH levels found in heavy road traffic [47]. This high local level of PAH is likely due to liquid grease

droplets falling into the gas flame or onto heated charcoal briquets. Vaporization or splattering of these grease droplets influences combustion, which likely follows a similar pattern to liquid-diffusion combustion.

Because of their broad use, there is significant interest in the development of burners that are robust, energy-efficient, compliant with pollutution emission regulations, and process friendly. In addition, multifuel capability and advanced flame-management systems are desirable to render them reliable and safe. The resulting furnaces are expected to process products uniformly and efficiently, and be cost effective with minimal fuel consumption and environmental impact. Boilers similarly are expected be fuel-flexible, cost effective, reliable, and safe.

[Top of Page]

3. Nonconventional Combustion

Nonconventional combustion processes do not involve flames or high temperatures in converting fuels into carbon dioxide and water. Significant attributes of some of the nonconventional combustion processes include the generation of little or no pollution, and higher energy conversion efficiencies compared to conventional combustion. Examples of nonconventional combustion processes include catalytic combustion and fuel cells. In addition, it is also possible to view biological processes, in particular cellular respiration, as a combustion process that converts carbohydrates such as sugars, into CO_2 and H_2O. However, the discussion of these biological processes is beyond scope of this chapter.

3.1. Catalytic Combustion

Catalytic combustion represents an attractive alternative technology to conventional combustion in which the formation and emission of pollutants such as NO_x, CO, UHC, PAH, and soot are significantly diminished. Gaseous fuels such as natural gas are most commonly used in catalytic combustion. The technology is applied broadly, from large-scale industrial gas-turbine combustors and boilers to small-scale heat generators such as residential boilers, heaters, and stoves. Besides low pollutant emissions, and hence high fuel conversion efficiencies, catalytic combustors also have the ability to operate over a wide range of equivalence ratios and power modulations, i.e., turndown ratios. Consequently, they are also used as afterburners to clean up pollutants in conventional combustion effluents.

Fuel oxidation in catalytic combustion is achieved through the participation of a solid catalyst, usually at temperatures below 1000 °C (Fig. 18). Combustion catalysts generally are metals supported on high surface area ceramic substrates, such as Al_2O_3, ZrO_2, MgO, or mixtures thereof. Active metals used as catalysts include Pt, Pd, Cr, and Rh. Because the catalyst provides a large thermal inertia, stable catalytic combustion can be achieved over a very broad range of conditions. The fuel and oxygen first diffuse to and then are adsorbed on the catalyst surface, followed by surface-catalyzed oxidation processes. The reaction products then desorb from the surface, regenerating the catalytic sites. Because of the close proximity of the fuel and oxygen on the catalyst surface, reactions achieve a higher degree of completion in catalytic combustion. As is the case with char combustion, catalytic combustion rates also exhibit different regimes of operation. At low temperatures (e.g., 100 – 300 °C), surface reaction rates are low relative to diffusion rates, and thus surface kinetics dominate the overall rate of combustion. However, at temperatures above several hundred degrees celcius, the rates of surface reaction become so large that the diffusion of reactants to the catalyst surface becomes the rate-limiting step in the combustion process. Generally, practical catalytic combustors are operated in the diffusion-controlled regime below 1000 °C. Consequently, thermal NO_x formation is virtually avoided in catalytic combustion. In addition, both prompt and fuel NO_x formation is reduced because fuel radicals are not released from the surface of the catalyst until they are completely oxidized to CO_2.

Figure 18. Catalytic combustion produces less pollutants than flames over a broader range of operating conditions

In addition to being utilized in a stand-alone device, catalytic combustion can also be used in conjunction with conventional combustion systems to stabilize premixed flames at lower temperatures. This is achieved by catalytically prereacting, and thus preheating, a portion of the fuel – air mixture entering a gas-phase combustion device. Preheating allows the stabilization of flames at equivalence ratios lower than otherwise possible, and thus extremely fuel lean and stable operation becomes feasible. The creation of reactive intermediates such as partially converted hydrocarbons or radicals in the prereaction process also stabilize the downstream flame. Depending upon the method of operation, flames can be catalytically stabilized at temperatures below 1300 °C. Thus, catalytic flame stabilization has an advantage over conventional lean premixed systems, in which combustion stability and increasing CO/UHC emissions become problematic at the low flame temperatures required for low NO_x emissions over a wide turn-down range (see Fig. 5). Additionally, premixed combustion is prone to combustion-driven acoustic oscillations or vibrations, which can affect flame stability and combustor life. By stabilizing the rate of gas-phase energy release in the combustor, a catalytic pre-reactor can significantly improve the performance of a lean premixed combustion system with respect to combustion dynamics.

The catalysts can be located either directly in the combustor itself or upstream of the combustion zone. In either case, the catalyst is located downstream of the fuel and air injection point, so that premixed fuel and air react as they pass through the catalyst bed. Some degree of gas-phase reaction, including CO burnout, generally is permitted downstream of the catalyst, so that the catalyst bed can remain small in size and 100 % catalytic oxidation is not required.

Durability is the overriding issue in catalytic combustion, because many metals exhibit good total oxidation characteristics. Since exposure to high temperatures, e.g., 1300 – 1800 °C, is a potential problem, innovative reactor designs become necessary to maintain the catalyst at more reasonable temperatures (e.g., < 1000 °C) where the catalyst can remain operational for tens of thousands of hours without deactivation.

Another significant challenge for catalytic combustion is the potential for severe thermal shock during rapid startup and shutdown processes. For example, the temperature of the catalyst can decrease at a rate of thousands of degrees per second when the fuel flow is abruptly stopped and air continues to flow over the catalyst, as can be the case during an emergency process shut down. Alternatively, the catalyst temperature can rapidly rise by 500 – 1000 °C when the system starts up or when additional fuel is rapidly injected. A catastrophic failure of the catalyst substrate is not acceptable because of the possibility of damage to the combustion hardware components, such as gas turbine blades, downstream of the catalytic reactor. Therefore, it is generally preferred to use metallic substrates or special packaging for ceramic substrates that accommodates their thermal fragility. The tradeoff of using metallic substrates is their lower thermal resistance in the demanding environment of a combustor. This requires the use of high temperature metal alloys containing Fe, Ni, Cr, Al. Other substantial issues with catalyst stability include sintering, adhesion, and volatilization [48-50].

3.2. Fuel Cells

Fuel cells (⟶ Fuel Cells) Fuel Cells convert the chemical energy of fuels directly into electrical energy using a catalytic electrochemical process. They provide a clean and highly efficient source of electrical energy, potentially to power vehicles and replace conventional combustion in power generation applications. Although fuel cell research dates back at least 30 years and was discovered nearly 100 years ago, automakers only recently have begun taking serious steps to develop fuel-cell-powered vehicles. Fuel cells are one of the cleanest and most efficient technologies for generating electricity. Since there is no flame formation, fuel cells do not suffer from any of the pollution problems associated with conventional combustion devices such as internal combustion engines, boilers, furnaces, and gas turbines. For fuel cells designed to utilize hydrogen directly, the only products are electricity and water, and small quantities of heat. Fuel cells also have very high energy conversion efficiencies. For example, they are 2 – 3 times more efficient than an internal combustion engine in converting fuel to power since they are not limited by the Carnot cycle.

When natural gas or other hydrocarbons are used, fuel cells produce some carbon dioxide. Advanced fuel cells using natural gas, for example, could potentially reduce carbon dioxide emissions by 60 % compared to a conventional coal plant and by 25 % compared to natural gas plants because of their high efficiencies. Moreover, the carbon dioxide is emitted in a purer form which makes its capture and sequestration much easier. Water is the only emission when hydrogen is the fuel.

In a fuel cell, hydrogen gas from the fuel reacts electrochemically (catalytically) at one of the electrodes (anode) and is transformed into protons and electrons, as shown in Figure 19. The protons move through an electrolyte to the other electrode (cathode), where they combine with oxygen from the air and with electrons to form water, which is expelled from the cell as vapor. The involvement of hydrogen and oxygen in the two reactions - one releasing electrons and the other consuming them - yields electrical current that can be tapped across the electrodes for power, as shown in Figure 19. Typically platinum is used as electrochemical catalyst both at the anode and cathode. Since fuel cells utilize highly selective catalysts and low temperatures (about 80 °C), the formation of NO_x is totally avoided. Since fuel cell catalysts are susceptible to sulfur poisoning, the fuels used must be processed to remove even trace of sulfur compounds. Therefore, fuel cells also are free from SO_x emissions. Finally, the production and emission of PAH, soot, and PM are negligible in fuel cells because of the mild operating conditions.

The largest barrier to the wide spread use of fuel cells is their cost of production and daily usage. First, fuel cells utilize substantial amounts of expensive platinum as catalyst, for which there is an uncertainty with regard to its worldwide supply. For example, according to one study, the displacement of conventional transportation by fuel-cell-powered vehicles in 66 years would require nearly 50 % of the world production of platinum, which must also be increased by 2.5-fold [51].

Figure 19. Operating principle of the hydrogen polymer electrode membrane fuel cell.

Second, the lack of readily available hydrogen, both as an inexpensive resource and distribution infrastructure, will also significantly add to the routine use of fuel cells in society. In fact, recognizing the infrastructure problem, current fuel cell research also addresses the on board creation of hydrogen from liquid fuels, such as gasoline, liquified natural gas, and alcohols. This requires the implementation of a catalytic reforming technology to convert these hydrocarbon fuels into hydrogen for fuel cell use and carbon dioxide, which must be vented. Thus, fuel cells using hydrocarbon fuels would continue to emit greenhouse gases.

In conclusion, only when inexpensive, nonhydrocarbon-based sources of hydrogen can be created, and ways to safely store and transport are developed, will fuel cells become viable enough to challenge conventional combustion systems. Even then, the question of availability of platinum must still be addressed.

1. Introduction

The use of electricity for thermal heating offers a number of techniques applicable to a wide range of materials (Table 1). Direct heating involves applying a voltage, or equivalently an electric field, across the material to be heated (workpiece) causing an electric current to pass through the product. Energy is dissipated as heat due to the resistance that the material offers to the current flow. With indirect heating, energy is transferred from an electrically heated element to the product by thermal conduction, convection, or infrared radiation. The techniques to be discussed are distinct from those where energy is absorbed directly by intermolecular bonds to cause specific reactions without the body as a whole heating up. Applications where electricity is used indirectly in a heating system to provide the motive force, for example, electrically driven heat pumps, also are not discussed.

Electrical heating is commonly perceived to be expensive in comparison with other methods. While this can certainly be true, electrical techniques should not be rejected before an appraisal has been made: their advantages can radically improve a process and can far outweigh initial considerations of capital and operating costs [1, 2]. The general advantages of electrical heating are:

1) Rapid start up

Table 1. The range of electrical heating techniques

Technique	Type of material treated	Applications
Direct resistance	good electrical conductors	heating metals, melting glass, sterilization and cooking of foodstuffs
Indirect resistance	all materials	all forms of heat treatment, trace heating, ovens and furnaces
Infrared	all materials that absorb IR	drying and curing of surface finishes, drying of sheet material
Direct induction	metals, good conductors	metal melting and surface treatment
Indirect induction	all materials	heating materials in metal vessels, drying and calcining
Dielectric	lossy dielectrics, very poor electrical conductors	drying, food processing
Plasma arcs and torches	metals, nonmetals	welding, cutting, metal melting and refining
Electron beam	metals, nonmetals	welding, cutting, drilling
Lasers	metals, nonmetals	cutting, drilling, surface treatment

2) Capability of automation and accurate control of the process parameters
3) Clean working environment with no products of combustion
4) Large power densities, hence smaller equipment
5) Improved product quality

2. Resistance Heating

2.1. Direct Resistance Heating of Electrically Conducting Materials

Principles. The simplest way to heat an electrical conductor is to connect the leads from a line (mains)-frequency power supply across the ends of the product and use Joule or Ohmic heating arising from the electrical resistance R (Fig. 1). The time-averaged power dissipation is given by

$$P = 0.5 I^2 R = 0.5 V^2 / R \tag{1}$$

Figure 1. Principles of direct resistance heating (schematic); I current, V voltage, A cross-sectional area, l length of conductor (workpiece)

The second relation is obtained from Ohms law relating the applied voltage V to the current I flowing through the resistance R:

$$R = V / I \tag{2}$$

where V and I refer to peak values. At line frequencies the power is distributed uniformly throughout the volume of the material. Large powers can be obtained by increasing I and R. While the currents used can be as high as 10^5 A, considerations of economy and safety regarding the voltage impose an upper limit on the permissible value of R. The resistance is related to the resistivity of the material ϱ, length of the conducting path l, and cross-sectional area for current flow A by

$$R = \varrho l / A \tag{3}$$

Ideally, for a given volume the workpiece should be long in proportion to its cross-sectional area to maximize the value of R. Good electrical contact must be made between the supply leads and the workpiece; otherwise, localized overheating at the contacts can result, and the voltage required for heating is greater than really necessary.

Applications. This form of heating is used extensively in the metals industry for preheating and annealing. A less common application is in the direct heating of metal pipelines to improve the transport of viscous materials [1, pp. 303 – 321].

For heating liquids, these methods are employed in the melting of glass, the treatment of metal components in a heated molten salt bath (typically 100 L in volume with up to 100 kW power input), and the rapid generation of relatively small quantities of hot water or steam in compact electrode boilers (40 – 2500 kW power input). Another application is the sterilization and cooking of pumpable, semiliquid foodstuffs in continuous flow, with powers of up to 0.5 MW envisaged [3]. Such foodstuffs and industrial water supplies usually have enough dissolved salts present to make the product sufficiently electrically conducting for Ohmic heating purposes. Alternating currents and voltages must be used to avoid unwanted electrolytic effects.

2.2. Indirect Resistance Heating of Materials

Principles. If a directly heated metallic element is placed in contact with a workpiece, then heat is transferred to the latter by thermal conduction. Alternatively, if the element is mounted in an enclosure, heat transfer can occur by natural or forced convection, and infrared radiation. Only a small number of materials are suitable for the actual electrical resistor: nickel and iron alloys, for example, Nichrome, the so-called refractory metals, and at operating temperatures

above 1000 °C, some nonmetals such as silicon carbide and graphite, which are electrically conducting at these temperatures.

In use, the electrical conductor (element) may be left exposed, as in some air heaters, but more often it is held on a former within a metal sheath with powdered electrical insulation between the element and sheath. Flexible heaters can be formed from carbon loaded rubber and plastics, some "self-regulating" semiconductors, insulated wire ribbons, or meshes woven into or held on a fabric support. Power densities are typically 2 – 60 kW/m^2, depending upon the application. However, larger values are possible with specially designed cartridge heaters.

Applications. Indirect resistance heating is the most widely used form of electrical heating with loads ranging from a few watts up to a megawatt. A large proportion of applications however require less than 10 kW. In these circumstances, operating costs are often not important, and the advantages of low capital cost, good control, absence of combustion products, a high degree of flexibility, and safe operation in flammable areas can be exploited. The applications are too diverse to list individually. This technique is used in all forms of heat treatment, e.g., annealing, forging, stress relieving, and hardening of metals; firing, glazing, enameling, sintering, drying, baking, cooking, and melting of nonmetals [1, pp. 321 – 419]. Such versatility is possible because most materials can be raised to the required temperature if heated in a hot air stream or infrared beam for long enough. That is not to say that this method is the most appropriate in any given situation. Indirect resistance heating may be classified according to the method of application: cartridge, surface and immersion heaters, batch and continuous ovens, and furnaces.

Cartridge heaters are used to provide high-intensity localized heating by thermal conduction to dies, nozzles, platens, and blades. This is achieved by constructing the heater so that both the internal and external thermal resistance are minimized. In this manner power densities of 1 MW/m^2 can be obtained.

Surface heaters allow uniform heating, with large overall power inputs, but at modest power densities so that there is no danger of hot spots. Sheathed heating elements can be attached to the sides of metal vessels, or in the case of cylindrically shaped containers they can be arranged on a metal former, which can then be clamped on. Flexible resistance heaters are used to provide contact (trace) heating of valves and pipes in chemical processing plants to compensate for heat losses or assist the transport of viscous materials. Self-regulating heating tapes, which have the ability to decrease their power output as the temperature rises, are available for some trace heating applications.

Immersion heaters, commonly using metal sheathed elements, are used to heat liquids, gases, and soft metals with melting points below 650 °C at efficiencies close to 100 %. The power densities that can be achieved are generally limited by the thermal resistance at the sheath interface with the material. The heater elements in a U or W shape can be flange-mounted into the side of the holding vessel or, alternatively, may be hung from the top. Heaters in the form of a spiral with additional metal fins to increase the available heat transfer area can be mounted in ducts to heat air and other gases to high temperatures.

Electric ovens and furnaces are competitive with comparable fuel fired systems because of the general advantages mentioned above and their efficiency of electrical energy utilization: 40 – 60 % for an oven, 70 % for a tunnel furnace. The term furnace applies to equipment operating above 500 °C. An oven consists essentially of a double skinned metal chamber with thermal insulation sandwiched between the skins. Electric heating elements are mounted either in the oven, with suitable baffles and shields to direct the air flow over them, or externally in connecting ducts. The distribution of heaters and baffles is arranged to obtain the desired heating pattern. Fans are used to provide a forced draft of air. This type of construction can be used up to ca. 700 °C, but at higher temperatures refractory materials are required to line furnaces to provide the necessary insulation.

Heat transfer occurs by conduction through the workpiece supports, natural or forced convection, and radiation. While natural convection ovens are the simplest in terms of construction, forced convection is often to be preferred since greater heat transfer and better temperature control are possible. Radiation becomes the dominant mode of heating at temperatures above

Figure 2. Batch furnace operating at 950 °C

500 °C for natural convection and 700 °C for forced convection. Where radiation is the principal mode of heat transfer, the furnace is built with the heating elements distributed so that the temperature of the inner furnace lining varies as little as possible to enable uniform radiant heating. Many designs of oven and furnace are possible depending upon the requirements: batch (Fig. 2) or continuous operation; front, top, or bottom loading; horizontal or vertical forced convection; transportation of the product by trolley, rollers, or various types of belt conveyor; operation under vacuum or in a specially controlled atmosphere, or the need for a well-defined processing temperature.

3. Infrared Heating

Principles. Any hot body will emit infrared (IR) radiation. The hotter the body, the smaller the wavelength at which the maximum energy is emitted and the greater the energy density (→ Radiation Heating). Electric infrared power sources utilize a heated electrical element, often sheathed within another material, to produce radiant heat. Details of typical sources are shown in Table 2. Elements are classified as short, medium, or long wave according to the element temperature, or equivalently the peak wavelength. The higher the operating temperature of the element, the greater the proportion of the electrical energy that is dissipated as infrared radiation. The remainder heats the surrounding air by convection. Emitters can be used individually, or more commonly, in modules with built-in reflectors. The modules in turn can be arranged to give the required energy profiles for the particular product concerned. Infrared radiation can be focused and reflected in the same manner as light waves, which enables power to be concentrated and transmitted relatively simply. Conversely, with irregularly shaped materials heating can be uneven due to portions of the product lying in shadow. The technique is better suited to continuous processes, with flat or regularly shaped products.

The efficiency of heating a product with infrared radiation depends on the ability of the material to absorb rather than reflect radiation at the peak wavelength of the emitter. Consequently, a knowledge of the absorption as a function of wavelength is desirable. As a rough guide, metals absorb radiation at wavelengths below ca. 1 μm, while nonmetals absorb at wavelengths above this. For most practical purposes the IR absorption can be regarded as occurring at the surface of the material. With some food prod-

[a] SW Short wave; MW Medium wave; LW Long wave.
[b] Measured close up to element.
[c] Forced air cooling preferable above 40 kW/m^2.
[d] 5 – 30 W/mm^2.
[e] Life is longer if gun is used at reduced voltage.

ucts, however, the radiation can penetrate several millimeters before all is absorbed.

The choice of emitter in a given application is determined not only by the absorption characteristics of the workpiece but also by the process conditions, e.g., the presence of mechanical vibration, the possibility of surface contamination, and the need for fast shut-down in the event of an interruption to the process. Some compromise between these various factors is often required. Most materials, excluding metals, cannot absorb more than 15 – 20 kW/m^2 without sustaining damage. Consequently an installed power density of not more than 20 – 25 kW/m^2 is advisable.

Applications. There are a wide variety of uses, which can be grouped into three main areas: drying and curing of paints, inks, resins, and other finishes; mass heating ranging from plastics molding to sterilization; and moisture removal from, for example, webs and granular material. The design of the equipment ranges from relatively simple modules to complex computer controlled installations. Examples are belt-conveyor and tunnel ovens, double sided panels for on-machine mounting, and static panels for even heating of large areas [4].

An important development is the manufacture of elements consisting of short-wave lamps and panels of very low thermal mass material. These panels can absorb the short-wave IR radiation reflected from the product and re-emit radiation at longer wavelengths. This results in an efficient, fast response emitter. Such advances, together with improvements in sensing, enable much more precise control of power levels throughout the process and consequently new opportunities for this form of heating are appearing.

4. Induction Heating

4.1. Direct Induction Heating of Metals

Principles. Induction techniques enable a voltage to be applied directly across a workpiece without the need for connecting leads from the generator [5]. This is achieved by utilizing a basic result of electromagnetism, namely, that a magnetic field that changes with time generates a voltage in a circuit. The technique is similar to that used in a transformer and can be explained with reference to Figure 3A (see next page). A time-varying magnetic field is produced in the primary coil by an alternating current from the power supply. A second coil is positioned so that the changing magnetic field passes through it to produce a voltage, which in turn gives rise to a current *I,* often referred to as an *eddy current,* in the secondary circuit. Energy is dissipated in the resistor R by Ohmic heating (I^2R). Taking the heating of a metal cylinder as an example (Fig. 3B), the workpiece forms the secondary circuit and is placed within the primary coil to ensure good penetration (linkage) by the magnetic field. The metal cylinder corresponds to a single-turn coil with the resistance distributed throughout.

Figure 3. Direct induction heating
A) Principles of operation; B) Application to a cylindrical workpiece; *I* current produced in workpiece, *R* resistance of workpiece

An important characteristic parameter is the skin depth δ (in m) given by

$$\delta = 503\sqrt{\varrho/\mu_r f} \tag{4}$$

where f = frequency of the alternating current, Hz; ϱ = the resistivity of the material, Ωm; μ_r = the relative magnetic permeability of the material. The significance of δ lies in the fact that most of the induced current in the workpiece, and hence the power dissipation, is found within a region extending from the surface of the material to about one skin depth below. In addition, the power dissipation per unit surface area of the material is inversely proportional to δ. Two of the major objectives when designing induction heating equipment are to ensure that (a) the energy is dissipated in the desired manner, that is, surface or volumetric heating and (b) that linkage of the magnetic field to the workpiece is adequate to give efficient energy transfer. As the physical properties of the workpiece are fixed, the only available variable is the operating frequency. For efficient operation, as the diameter of the workpiece decreases, the frequency used must increase. The three frequency bands employed are:

Line frequencies	50 – 60 Hz
Medium frequency	500 – 10 000 Hz
High frequency	100 kHz – 5 MHz

Applications. Induction techniques are used extensively in metal melting and volumetric and surface heat treatment of metals to modify the physical properties, e.g., surface hardening. Localized heating is used in brazing, soft soldering, and welding, where the fast heating rates can minimize oxidation and distortion. These applications are covered thoroughly in references [5, 6].

4.2. Indirect Induction Heating of Materials

Principles. Induction heating is used to heat a metal surface, which in turn heats the product through thermal conduction. The lack of electrical contacts and the absence of a flame or products of combustion can be used to advantage to heat nonmetallic materials.

Applications. The heating of material, e.g., paint, within a large metal vessel can be achieved simply by winding the primary coil around the vessel, which acts as the secondary coil [5]. The power densities required are usually modest and line frequencies can be used. Such heaters in the range 10 – 250 kW are available and are to be preferred for power densities greater than 10 kW/m^2. Below this, resistance and steam heating are more economical. A related application is the use of induction methods for heating the surface of metal drum containers.

The rapid but controlled heating obtainable with induction heating can be applied to molding and extrusion processes. The induction heaters are built into mold platens or wrapped around the barrels of extrusion machines.

Indirect induction methods provide a convenient source of heat for direct contact drying. A

Figure 4. 100-kW rotary induction heater for contact heating of granular material

most dramatic example of this was the drying of paint on the metal surface of an entire railway carriage [6]. The attraction of drying paints and varnishes in this way is that the heat comes from below so that a surface skin does not form and volatiles can escape. The lack of electrical contacts has been exploited in a range of rotary dryers and calciners (Fig. 4) [7]. The material is transported and heated by rotating fins in the usual way. The fins themselves, however, form part of the secondary coil and are inductively heated at line frequency. Large power densities, up to 16 kW/m^2, and fine control of the fin temperature are possible, enabling temperature sensitive products to be dried.

5. Dielectric Heating of Nonmetals

Principles. Dielectric heating provides a method of contactless, direct, volumetric heating of suitable lossy dielectrics (dielectric materials capable of absorbing electromagnetic energy) and very poor electrical conductors [8]. This is achieved by the application of a time varying electric field generated either at radio frequencies (rf) or microwave frequencies.

In dielectric materials, which are nonconductors, there are no conduction currents. Instead there is a so-called displacement current, related to the time varying electric field and the dielectric properties of the material. For many dielectrics that are good electric insulators, such as some ceramics, this current gives rise to negligible heating. However, significant energy dissipation in lossy dielectrics can occur by several physical mechanisms.

Of most practical interest is the behavior of polar dielectrics: the permanent electric dipoles attempt to align themselves with the changing electric field, so gaining energy, which is then lost as heat through collisions with neighboring molecules. Maximum energy dissipation occurs at a particular resonant frequency and is directly

proportional to a dimensionless quantity, again related to the dielectric properties of the material, called the loss factor ε''. For polar liquids such as water and many solvents this resonant frequency occurs in the microwave band. For solids, the resonant frequency is lower, and the energy dissipation is usually much less since the movement of the dipoles is constrained by the solid structure.

A poor electrical conductor of particular importance is industrial water, which generally contains sufficient dissolved salts to make it weakly conducting. In addition to the displacement current, a conduction current can flow and dissipation by essentially direct resistance heating can take place. In the present context, however, the practical techniques used to apply the electric field are those of dielectric rather than resistance heating: contactless capacitive coupling at high frequencies rather than direct electrical contacts. Consequently, the effects due to any dissolved salts are usually incorporated within the framework of dielectric heating and described in terms of an effective loss factor. It is the presence of dissolved salts, in fact, which makes possible the use of rf techniques for moisture removal.

Dielectric heating equipment can only be operated at certain frequencies to ensure that there is no interference with telecommunications. These permitted frequencies vary from country to country but the most common are

13.56 MHz ± 0.06 %
27.12 MHz ± 0.6 %
896/915 MHz ± 10/13 MHz
2450 MHz ± 50 MHz

The essence of radio frequency techniques is that an rf voltage is applied across the plates of a capacitor to give an alternating electric field (Fig. 5). The product is held or passed between the plates and heated by the mechanisms described above. The physical size and shape of the capacitor can be varied to suit the particular process subject to certain constraints related to the rf energy generation. The rf power output available from typical generators ranges from a few kilowatts to ca. 100 kW, although units up to 600 kW are available. Between 60 – 80 % of the rf output power reaches the workpiece, while the efficiency of energy utilization, in terms of the energy drawn from the line supply to that dissipated in the product, is between 45 – 55 %.

Figure 5. Principle of dielectric heating at radio frequencies

A common form of industrial microwave heater is basically an enlarged version of the familiar domestic microwave oven with product ports to allow continuous processing. The power sources, known as magnetrons, generate a microwave electromagnetic wave that excites the molecules, giving rise to energy dissipation as the wave passes through the product. Other forms of ovens, employing microwave horn antennas, single mode cavities, and slotted waveguides, are possible. At the operating frequency of 2450 MHz, the maximum power output available from a single magnetron is 6 kW with an overall efficiency (line input to product) of ca. 65 – 70 %. Improvements in magnetron design at 896/915 MHz have resulted in the availability of 60 kW magnetrons of high overall efficiency of the order of 80 %.

Applications. Despite the high capital cost of these techniques, they are widely used in certain areas, notably the textile and food industries. Their appeal lies in the direct volumetric heat transfer, which can eliminate limitations due to thermal conduction within the material and, in the case of moisture removal by evaporation, can give rise to internal evaporation and enhanced internal moisture flow. The most important consideration in existing commercial installations appears to be the improved product quality arising from this unique form of heat and mass transfer.

In the past, rf techniques have been used more for plastics welding and moisture removal applications, while microwaves have been used mainly for cooking and food processing, such as melting, thawing, and blanching, and more recently vacuum drying of high-value materials.

Figure 6. Radio frequency assisted convection band dryer as used in the food industry
Courtesy of Greenbank Engineering

The loss factor of wet materials increases with the moisture content. This variation is used to great effect to place the greatest amounts of heat into the initially wettest parts of the material. This leads to increased local evaporation and a leveling out of moisture profiles, giving improved product quality. This feature is used extensively in textile, paper, and pasta drying and postbaking of biscuits.

Another approach, applicable to certain capillary porous products, is to combine rf or microwave heating with convective drying (Fig. 6) [8,9]. The internal evaporation and enhanced moisture flow due to the dielectric heating are used in such a way that the convective drying remains effective for a longer proportion of the drying cycle, as compared to convective drying alone. The benefits of this approach are smaller sized equipment, improved product quality, cheaper running costs, and a more favorable capital cost, since the rf or microwave component is kept to a minimum. These factors make this combinational technique attractive to a wider range of applications where pure dielectric heating alone might not be considered owing to its high capital cost.

6. Thermal Plasma Heating

Principles. A gaseous plasma is a mixture of ions, electrons, and non-ionized neutral gas capable of conducting an electrical current when a voltage is applied across it. The characteristics of the plasma depend very much on the operating regime, especially the pressure. For thermal processing, operation at atmospheric pressure is common [10]. The kinetic energy of the electrons is increased by the influence of the applied electric field on their motion. This energy is dissipated as heat as a result of the frequent collisions between the gaseous species, which are in thermal equilibrium with each other, hence the name *thermal plasma.* Temperatures of the order of thousands of degrees centigrade can be obtained. Unlike conventional oxy – gas flames, combustion does not occur: the

heat in the plasma "flame" is derived from the electrical power source. Such plasmas may be used as a source of heat, sometimes with one of the components taking part in chemical reactions; as an indirect source of radiation and resistance heating, the classical plasma arc; and as a direct source of hot gas, the classical plasma torch. The first application, while of immense interest, is, with few exceptions, in the preindustrial stage [11].

Applications–Direct Heating with a Plasma Torch. The plasma torch consists of an anode electrode in the form of a metal tube, shaped into a nozzle at one end, and an inner cathode electrode (Fig. 7A). Gas at slightly above atmospheric pressure passes between the electrodes, is ionized to form a thermal plasma, and issues from the nozzle as a high-velocity, high-temperature plasma "flame." This basic form of operation is known as the *nontransferred* mode with the majority of the current flow between the two electrodes. The other, *transferred mode,* is applicable to metal workpieces that are used as a third electrode in such a way that the workpiece rather than the nozzle acts as the anode (Fig. 7B). In the first case the maximum amount of input energy appearing in the plasma flame is ca. 65 %, with the rest dissipated as heat at the anode. With the transferred plasma torch the electrical energy utilization is 65 – 75 %, and powers of several hundred kilowatts can be used.

Welding with a transferred plasma torch has a number of advantages over tungsten and metal inert gas techniques (TIG and MIG): greater energy densities, more stable operation, higher flame heat content and velocity. These enable faster and deeper welds to be achieved [12]. The nontransferred torch can be used to spray materials, initially in powder form, onto surfaces to form coatings. Again, due to the high temperature and velocity of the plasma, this technique is particularly attractive for high melting point materials and those which would be oxidized or contaminated with flame spraying.

Transferred plasma arcs are capable of cutting any metal, unlike oxy – fuel cutting, but up to now have been used principally for stainless steel over 6 mm thick. High cutting speeds and good quality cuts can be obtained using air or most diatomic gases. A variant of cutting is plasma machining. A nontransferred torch is used to soften hard metals in front of the cutting tool to allow faster metal removal rates in turning operations.

Figure 7. Principle of a plasma torch
A) Nontransferred mode; B) Transferred mode

The need for the workpiece to act as a third electrode has limited the cutting applications of the transferred arc to metals. A nontransferred cutting torch potentially extends of this method to a vast range of nonmetallic materials [13].

Applications–Indirect Heating with an Electric Arc. Direct and indirect arcs are used for metal melting and refining. In the indirect form an atmospheric plasma is struck between two electrodes and the infrared radiation obtained from the high-temperature arc is used to melt scrap metal held in a refractory-lined container below. In the direct form the metal to be

melted forms an intermediate electrode and the plasma is struck between it and the other two electrodes. Heating arises from the IR radiation as before and from the resistance heating of the metal, which occurs due to the current flowing in the intermediate metal electrode. A variation on this form of arc is where the electrodes are actually submerged in the molten metal.

7. Electron Beam Heating

Principles. In a typical electron beam gun device, electrons from a heated cathode are accelerated in a vacuum by a large voltage (20 – 150 kV) applied to the anode. The beam of electrons is directed, and for some applications finely focused, on to the workpiece, which is heated by absorbing the kinetic energy of the bombarding electrons. Typically, the vacuum required is $10^{-2} - 10^{-3}$ Pa ($10^{-4} - 10^{-5}$ Torr), the electron currents range from tens of milliamperes to amperes, and the power in the beam varies from a few kilowatts to megawatts, with power densities up to 10^9 MW/m^2 [1, pp. 745 – 782]. An alternative source of electrons can be found in the cathode region of a glow discharge operating at higher pressures (ca. 10 Pa or 0.1 Torr), an anode voltage in the range 1 – 10 kV, and power densities of the order of 1 MW/m^2. These glow discharge guns produce a broad electron beam, typically 100 mm^2 in cross section and are intended for heat treatment.

Applications. The technique generally requires the workpiece to be contained within a vacuum chamber. Partly for this reason and the high capital cost, applications with the electron gun are confined to specialist high-quality welding, and to a lesser extent cutting and drilling, in the aerospace, nuclear, electronic, and automobile industries. Welds with deep penetration, narrow width, and minimal distortion due to the reduced heat input are characteristic of these techniques. Electron beams have been used to melt or refine metals requiring high temperature and high purity. Heat treatment, annealing, and sintering using electron beams have exploited effects due to the high power densities and rapid rate of localized cooling on removal of the beam, to give auto-quenching at the surface.

Electron beams are in use for curing inks, coatings, and glues by selective energy absorption, rather than thermal effects, with systems that allow the workpiece to be handled in a normal environment rather than under vacuum.

8. Laser Heating

Principles. Lasers require electrical energy to excite the atoms or molecules of the lasing medium into a thermodynamically nonequilibrium state, from which they are induced to decay in an ordered manner, emitting a near parallel, monochromatic beam of intense light [14]. For industrial purposes, interest lies in carbon dioxide and argon ion gas lasers and solid-state neodymium glass lasers with characteristics as shown in Table 3. As with conventional IR radiation the suitability of heating a product depends on its ability to absorb radiation at the frequency of the laser.

Applications. While the high capital cost limits these techniques at present to specialized cutting, drilling, profiling, welding, and surface treatment operations, their use is growing. In some respects, laser processing can be seen as an alternative to electron beam techniques, with greater flexibility because a vacuum environment is not needed. For some cutting operations, the laser is in competition with the plasma torch, which generally has a much smaller capital cost.

Table 3. Industrial lasers for heating applications

Laser	Operating wavelength, nm	Mean power, W	Application
Argon	351 – 529	2 – 20 cw	scribing microcircuits
Neodymium	1060	20 – 1000 cw 0.5 J at 50 Hz	cutting, drilling
Carbon dioxide	10 600	500 cw 20 000 cw	nonmetal cutting welding metal, cutting

cw continuously working

1. Introduction

Radiation is a broad term that includes ionizing X-rays, ultraviolet, infrared (IR), and visible light waves, radio frequency (rf) waves, and microwaves–all part of the electromagnetic spectrum shown in Figure 1. While X-rays and ultraviolet rays can be used for selective energy absorption, and rf and microwaves are used for volumetric heating, radiation heating is generally taken to mean heat transfer by thermal infrared radiation with wavelengths of a few micrometers. The principal means of obtaining such radiation is by heating an element to a temperature of the order of a thousand degrees centigrade using either a gas flame or an electric heating element (→ Electrically Generated Heat).

2. Principles

In contrast to all other forms of heat transfer, radiation heating is a two-way process: the material to be heated (the workpiece) absorbs infrared radiation from the heating element while simultaneously and independently emitting a smaller amount of radiative energy. Generally, not all the electromagnetic radiation incident on the surface of the workpiece is absorbed: some can be reflected and some transmitted through the material with further internal absorption, depending on the physical properties of the material.

A convenient concept is that of a notional body that absorbs all the radiant energy incident upon it–a so-called *black body.* Real materials can only approximate such a body but for initial engineering calculations the idea is useful. The radiative power emitted from a black body is a function of its absolute temperature T and wavelength λ. For a wavelength interval λ_1 to λ_2, this power in W/m^2 is given by

$$\int_{\lambda 1}^{\lambda_2} E_{\lambda,T}\,\mathrm{d}\lambda$$

where

$$E_{\lambda,T} = c_1\lambda^{-5} / [\exp(c_2/\lambda T) - 1] \tag{1}$$

and

$$c_1 = 3.742 \times 10^{-16}\ \mathrm{W\,m^2}$$
$$c_2 = 1.4388 \times 10^{-2}\ \mathrm{m\,K}$$

Curves of the function $E_{\lambda,T}$ and the above integral can be found in standard texts, for example [1].

The total emitted radiant power is found by integrating the emissive power $E_{\lambda,T}$ over all wavelengths to give the Stefan – Boltzmann equation

$$E_\mathrm{b} = \sigma T^4 \tag{2}$$

where $\sigma = 5.6697 \times 10^{-8}\ \mathrm{W\,m^{-2}\,K^{-4}}$

At a particular temperature, the wavelength corresponding to the peak power density is obtained from Wien's law:

$$\lambda_\mathrm{max} T = 2.8979 \times 10^{-3}\,\mathrm{mK} \tag{3}$$

For a real material, both the emissive power and the absorbed power are less than that of a

Figure 1. The electromagnetic spectrum, showing the physical mechanisms for emission and absorption of radiation over the spectrum and the range of radiation heating

black body. It is useful to express these powers as a proportion of that which would be emitted or absorbed by a black body at the same wavelength and temperature–the emissivity e_λ and absorptivity α_λ, respectively, where $e_\lambda = \alpha_\lambda$ and $e_\lambda,\ \alpha_\lambda \leq 1$. These parameters can be strong functions of wavelength and temperature, and for practical heating applications, the absorption bands of interest lie in the infrared micrometer wavelength range. The object in designing efficient heating systems is to match, as closely as practicable, the peak emissive power of the heating source with the absorptivity of the material to be heated.

In order to gain some estimate of the net heat transfer to a body, it is usual to first consider the case of two infinite, parallel black bodies at temperatures T_1 and T_2 taking, for example, T_2 to be the temperature of the heating source. Then, the net heat transfer per unit area (in W/m^2) to the body at temperature T_1 is given by

$$\sigma\left(T_2^4 - T_1^4\right) \tag{4}$$

For other shapes it is necessary to multiply the above expression by a viewing factor F, where $F \leq 1$, which accounts for the fact that not all the radiation from one body falls onto the other. Values of F for different geometries are tabulated in standard works [1,2].

Sometimes it is possible to assume that the absorptivity and emissivity are independent of wavelength–a so-called *gray body.* An expression for the net power transfer analogous to Equation (4) is available in the literature [2]. However, this concept of a gray body is of limited use for many practical applications where the wavelength dependence of the parameters cannot be ignored, e.g., in moisture removal.

3. Applications

For most purposes, absorption of infrared radiation occurs at or near the surface of the product and thereafter relies on thermal conduction to transmit the heat. The heating elements used are classified as short, medium, and long wave, with peak emissive power at approximately 1, 2.5, and 3 micrometers, respectively. The power density obtained from these elements ranges from 10 – 400 kW/m^2 as measured close to the element and diminishes with distance from the source [3]. Many materials, with the exception of metals, cannot sustain more than 15 – 20 kW/m^2 at their surface without damage [4]. Present uses lie mainly in three areas: drying and curing of paints, inks, resins, and other finishes; mass heating; and moisture removal from webs and shallow granular beds. At the moment, electric rather than gas-fired elements are more common owing to their cheaper capital cost, simpler construction, and ease of application (→ Electrically Generated Heat). The main

obstacles in the use of infrared radiation in some areas where it should be the preferred method, e.g., in the heat treatment of textile webs, have been the slow response of the emitters, that is, the time to heat up or cool down from their operating temperature, and the uneven heating obtained. Developments in both gas and electric infrared elements, combined with the use of sensors and computer control, are overcoming these limitations so that greater exploitation of these techniques should be possible.

1. Introduction

A common denominator runs through all cooling towers whether they be large units in chemical plants circulating 76 000 L/min [20 000 gallons per minute (gpm)] of water, huge electric power plant natural-draft towers cooling 380 000 L/min (100 000 gpm), or small retail-store 5-ton refrigeration units with a 60-L/min (15-gpm) circulation rate. The common denominator that cannot be ignored in all of these systems is *waste heat*.

This problem is enormous because industry uses ca. 2.0×10^{12} L (500×10^{9} gallons) of water a day, which if not recirculated would seriously deplete the world's available water supply. Unwanted excess heat from the water must be released to the environment without creating ecological havoc or adding unnecessary expenses.

Cooling towers solve the problem of possible ecological damage from returning hot water to the environment and enable industry to recycle the greater part of the water it requires at reasonable capital investment outlays. Operating procedures, costs, and upgrading potential for greater efficiency must continually be investigated to provide economic returns for the installation. To achieve this intelligently, an understanding of the fundamental principles of cooling tower performance, plus the identification and comprehension of its various elements, are necessary to be able to upgrade them.

After the cooling tower has been erected, proper operation and maintenance are required to yield the design conditions of cooling. "By not maintaining towers adequately, they can lose appreciable performance as soon as they are started up" [2].

Too many engineers pay a minimum of attention to the cooling tower and are aware only of its being that "box in the back where we send the hot water and it comes back cold." Many managers are not concerned about the role of the cooling tower in their profit and loss [3].

The major profit area to be analyzed is utilization of the cold water. In a refrigeration or air-conditioning system, the colder the water, the lower is the energy required to power the equipment because of reduced head pressures and temperatures. An additional benefit of colder water is the extension of service life due to easier running of the machinery:

The cooling tower plays one of the key roles in the efficiency of your air conditioning machinery. The efficiency of the equipment is measured in kilowatt usage. If your tower does not create the proper heat transfer, your machine will work harder to compensate for the loss in efficiency [4].

In chemical manufacturing plants, colder water yields more efficient condensation, as well as greater volume and lower cost of salable condensate product. In power plants, colder water reduces the cost of the electricity used to produce salable or usable power (the electric generation penalty). The second area of profit to be considered is the electrical or steam dollar expenditure that is purchased to power the systems. The cooling tower is a high-energy-utilization machine as well as a mass- and heat-transfer device.

With regard to cooling towers, the manager and the engineer should have two basic goals: (1) understanding their cooling tower and (2) obtaining *colder water*.

2. Design

The criteria of cooling tower performance are outlined in the *design conditions* (Fig. 1) specified when the cooling tower is purchased or rebuilt; these designate the cooling of a specific

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.b03_17

quantity of circulating water from a particular entering temperature to a definite leaving temperature. The difference between these two temperatures is called *the range* or *delta T.* This cooling of the circulating water also must be performed at the stated wet-bulb temperature noted in the specifications. The difference between the cold discharged water and the wet-bulb temperatures is called the *approach* to the wet bulb.

Figure 1. Design conditions, the criteria for cooling tower performance specifications

Figure 2. Pressure – enthalpy diagram: its construction, use, and value [5]

A 1.0 °C colder water returned to the compressors and condensers in air-conditioning and refrigeration equipment, calculated from enthalpy charts (Fig. 2), amounts to ca. 3 % savings in electrical energy input to these machines (1 °F corresponds to 2 % savings) [6]. Therefore, water from the tower, which is colder by a little less than 2 °C, can save more than 6 % in electrical energy and resulting charges. A 1800-tonne (2000-ton) refrigeration system circulating 23 000 L/min (6000 gpm) could use $ 350 000 in electrical power a year. A 6 % savings of $ 21 000 is a significant factor in rapid payback for upgrading the tower.

3. Cooling Tower Fundamentals

The basic principles of cooling tower operation are evaporative cooling and exchange of sensible heat. The degree of evaporative cooling is determined by the difference between ambient and wet-bulb temperatures, which takes into consideration the temperature and dryness of the air: the wet bulb is a measurement of the ambient temperature and relative humidity or the ambient temperature and dew point. In practice, these relations are obtained by the use of a psychrometric chart. A portion of the water exposed to the moving air of the atmosphere evaporates, and as the water changes to vapor, heat is absorbed which amounts to ca. 2.3×10^6 J per kilogram of water (1000 Btu per pound of water) evaporated. The heat is taken from the water that remains, thereby lowering its temperature. This is evaporative cooling, an effect based on release of the latent heat of vaporization.

However, a penalty is involved, namely, the loss of water that is discharged from the cooling tower into the atmosphere as hot water vapor. Under normal operating conditions, this amounts to ca. 2.2 % for each 10 °C (1.2 % for 10 °F) of cooling. A tremendous quantity of water is lost through evaporation, which must be added to the system via makeup water: a 38 000-L/min (10 000-gpm) industrial 10 °F tower operating 24 h per day for ca. 300 days of the year would require 1.6×10^8 L (43×10^6 gallons) of water per year. By comparison, a small 4000-L/min (1000-gpm), 333-ton refrigeration system operating 12 h a day for six months of the year would require a makeup volume of 4.9×10^6 L (1.3×10^6 gallons) of water per year.

Sensible heat that changes temperature is also responsible for part of the cooling tower's operation. Sensible heat is heat that can be felt. Sensible heat exchange is the transfer of heat from the hot water to the cold air going through the tower. In a typical case, this represents ca. 20 % of the heat exchange in the cooling tower. The

Figure 3. Discharge plume: an indication that the evaporative cooling process is working

remaining 80 %, or the hard work performed in the cooling tower, is due to the evaporative cooling effect.

Hot always goes to cold, so if water is warmer than air, the air gets hotter as it picks up sensible heat from the water, and the water is cooled as its heat is transferred to the moving air.

Figure 4. Psychrometric analysis of air passing through a cooling tower: sensible heat exchange and latent heat of vaporization cooling [7]
Reprinted by permission of ASHRAE

Cooling due to evaporation amounts to ca. 75 % of the heat exchange in the cooling tower, while 25 % is sensible heat transfer. This ratio varies with the wet-bulb temperature, which is a measure of the evaporative capability available at a particular ambient temperature and dew point or relative humidity. Discharged moisture is visible as a plume or fog (Fig. 3) when the ambient temperature and dew point rise to 100 % saturation. Below that point, moisture is still being discharged, but it is invisible. Fogging can be predicted by drawing a straight line on a psychrometric chart (Fig. 4) from the tower's entering conditions to a point representing the discharge conditions. The greater the area of intersection to the left of the 100 % saturation curve, the more intense is the plume.

A cooling tower is "the heat rejection solution of the chemical process" or "correction of the heat penalty generation of compression equipment." The cooling tower is a machine that moves heat from point A to point B and ultimately discharges this heat into the atmosphere, which thermal engineers call a heat sink.

Psychrometric Analysis. The thermal performance of a cooling tower is affected by the entering wet-bulb temperature (WBT). The wet bulb is an important measurement of cooling tower performance. It determines the evaporative capacity available in the ambient temperature: 100 % wet bulb is 100 % saturation, i.e., fog or rain. The lower the wet bulb, the better the cooling tower functions. No cooling tower can cool water below the wet-bulb temperature.

In 1921, Merkel, a German physicist, developed the integration method of analyzing the driving force of a cooling tower, i.e., the difference in enthalpy between air saturated at the water temperature and the main airstream:

$$\frac{KaV}{L} = Me/c = \int_{T_2}^{T_1} \frac{\mathrm{d}T}{H'' - h}$$

where

$\frac{KaV}{L}$ = tower characteristic
Me = Merkel number

c = specific heat of water
T = bulk water temperature
T_1 = temperature in
T_2 = temperature out
H'' = air – water enthalpy at bulk water temperature
h = air – water enthalpy at wet-bulb temperature

The KaV/L, or cooling tower characteristic, is a measure of the order of difficulty for the cooling tower heat rejection requirements, independent of the fill performance. It is plotted logarithmically as the ordinate (vertical axis) on a design characteristic curve, with the liquid-to-gas (L/G) ratio as the abscissa (horizontal axis).

As an example, statements such as "this tower is not operating efficiently because it was designed for a 20 °F range and is only cooling an 18 °F range" and "this tower is doing quite well because it is rated for a 20 °F range and is cooling at a 22 °F delta T" may both be incorrect because neither statement mentions the WBT.

In the psychrometric schematic, Figure 4, when air enters at ambient point A, it absorbs heat and moisture from the water, exiting at point B in a saturated condition. The amount of heat transferred from the water to the air is proportional to the difference in the enthalpy of the air between the entering and leaving conditions ($h_B - h_A$). Vector AB may be separated into component AC, which represents sensible heat exchange, and component CB, which represents latent heat exchange.

If, at a higher entering air dry bulb, the condition is point D at the same wet-bulb temperature, but a different dry-bulb temperature, the total heat transfer remains the same, but the sensible and latent components have changed. The amount of evaporation depends upon the amount of sensible heating or cooling of the air, which in turn depends on the dew point.

The ratio of latent to sensible heat is important in analyzing the water usage of a cooling tower. Mass transfer (evaporation) occurs only in the latent portion of the heat-transfer process and is proportional to the change in specific humidity. Because the dry-bulb temperature or relative humidity of the entering air affects the latent : sensible heat-transfer ratio, it also affects the rate of evaporation. The rate of evaporation is less for vector AB ($w_B - w_A$) than for vector DB ($w_B - w_D$) because the latent heat transfer (mass transfer) represents a smaller portion of the total. At higher entering wet-bulb temperatures, the evaporative components are reduced because the specific humidity of the air is greater with less potential for evaporative cooling.

Counterflow vs. Crossflow. Cooling towers are available in two basic operational designs, counterflow and crossflow (Fig. 5). The main difference between them is that in counterflow towers, the air moves vertically through the fill, while in crossflow towers, it flows horizontally through the fill. In both cases, the water drops vertically through the fill after leaving the nozzle or water distribution area. In counterflow, the air and water mix at 180°, or counter to each other. In crossflow, the air – water mix is at 90°, or cross to each other.

4. Component Parts

All cooling towers, except small, packaged assembly-line air-conditioning models, are custom-made, and the manufacturer varies the shape, size, configuration, and input to meet the particular set of thermal parameters or design conditions required by the customer.

In both crossflow and counterflow towers, uniformity is the key to success: uniformity of water distribution, of static pressure, of fill configuration, and of air velocity (even though in a crossflow tower, the pressure differential will vary with the height). After installation, any operational deficiencies, such as clogged or broken nozzles and arms, broken or out-of-position decking fill, or drift eliminators with sections missing, will seriously affect optimization of the cooling tower's performance.

Wet Decking Fill. Generally the most significant improvements in thermal performance can be made simply by changing the wet decking fill. This, however, may not be done capriciously. Heat transfer must be investigated from a thermal engineering point of view, in conjunction with the fill characteristics. The manufacturer's performance curves are developed painstakingly by trial, error, and experimentation and are expressed as KaV/L or the heat-transfer characteristic [7]. Precise thermal, hydraulic, and

Figure 5. Cooling tower schematic configurations A) Counterflow; B) Crossflow

mechanical calculations should be performed to ascertain the maximum cold water available to optimize each individual design condition requirement [8, Chap. 9].

Figure 6. Splash bar cooling

Older, conventional fill consists of wooden slats. In wood slat splash bars (Fig. 6), droplets of water bounce from one layer of wood to the next, and rising air cools the outside of each sphere of the water droplets. Usually, however, the interior of the droplet retains some residual heat.

Figure 7. Cellular fill cooling

Modern state-of-the-art cellular fill (Fig. 7) takes the same droplet of water and spreads it

out in a very thin film, where the air can affect the entire surface of the film. Considerably more surface is available to the flowing air for evaporative cooling and sensible heat exchange to occur. The cellular fill pack contains more surface area than splash bars. Because the design of cellular fill permits air to flow through it with less total static pressure, it is extremely efficient, compared to the old-fashioned splash bar mixture system, for the same parameters of cooling.

For *crossflow towers* up to ca. 6 m (20 ft) in height, installation of cellular fill packing is economical. This provides the advantage of a high rate of cooling through the interaction of film fill and cooling air. In crossflow towers higher than 6 m (20 ft), the economic advantage and water loading per square foot favor the new shaped PVC [poly(vinyl chloride)] bars, which can be retrofitted to obtain higher levels of cooling. These bars are suspended on galvanized, bonderized, and PVC-coated wires, and several shapes are available from various manufacturers (Fig. 8). In changing any type of fill, whether cellular or shaped PVC splash bar, the fill manufacturer should be asked to provide thermal performance curves for their materials that have been tested and verified.

Figure 8. Shaped PVC fill bars designed for large crossflow cooling towers

Water Distribution System. For maximum performance, the water distribution system must provide a uniform pattern over the fill for optimum air – water interface. Crossflow hot water is distributed through holes (metered orifices) that drop the column of water on to splash grids. When a nozzle is clogged, it leaves a dry spot on the fill, and air follows the path of least resistance, rushing up this dry spot, thus wasting energy and cooling potential. This splash column distribution is typical of crossflow towers. A new modification to help develop a more uniform pattern involves a target nozzle with a built-in splash device (Fig. 9).

Figure 9. Target nozzles with splash devices to assist in developing a spray pattern

Figure 10. Modern PVC piping and nonclog square spray nozzle

In counterflow towers, rust and corrosion, typical of steel piping, cause breakage, with nozzles falling off. Wooden stave piping is also subject to breaking. A modern answer to the problem of deteriorated steel or wood piping is the use of PVC or fiberglass materials in conjunction with the ABS (acrylonitrile – butadiene – styrene) plastic square-pattern spray nozzle, which was de-

signed specifically for cooling towers and is practically clog-free (Fig. 10).

Drift Eliminators. A baffle, or drift eliminator, is placed between the water distribution system and the air discharge point to minimize dispersal of water droplets entrained in the airstream, into the surrounding atmosphere. Drift eliminator efficiency is an essential element of cooling tower design for many reasons: (1) conservation of water, (2) retention of chemical treatment in the cooling water, (3) prevention of staining by chemical additives such as chromates, and (4) compliance with local environmental-protection regulations.

Figure 11. Schematic three-pass wooden drift eliminator slats

Figure 12. Schematic six-pass cellular PVC drift eliminator

Cooling tower performance, i.e., heat removal, is a balance between water flow and air volume; therefore, drift eliminators are normally designed to be efficient through a calculated range of air flow. Too great an air speed can result in excessive drifting of water from the tower, while poorly designed eliminators increase static pressure through the tower, thereby slowing the air flow and lowering the cooling capability and efficiency of the unit.

An efficient mechanical system for retaining water is necessary because the spray or water distribution system turns the heavy stream of condenser or process water into light droplets preparatory to cooling by the airstream. As the air moves counterflow or crossflow to the water, it picks up some mist or droplets and can carry them with the air flow out of the tower.

The schematic operation of a three-pass drift eliminator is shown in Figure 11. A newer, more efficient drift eliminator fabricated from self-extinguishing PVC has been developed. It causes the air to gently change direction approximately six times, thereby obtaining greater surface contact to release water droplets. Figure 12 illustrates the schematic mechanics of the six-pass cellular drift eliminator.

A common way of attempting to improve cooling tower performance is to increase air velocity by rotating the fan with more power and higher pitch angle to the blades. This often causes increased drift loss because the eliminators were not designed for this type of service. Cellular drift eliminators that do not increase the static pressure but do increase the drift-collecting capability can minimize such an eventuality. In fact, reduced static pressure resistance allows more air to flow through the tower at the same power expenditure and permits more cooling at the same cost.

Complete drift elimination is possible in theory, but impractical in application. A generally satisfactory level is less than 0.02 % of the water volume.

Crossflow towers are often susceptible to drift problems because of a tendency toward higher air flow velocities in this type of design at the top of the tower. Cellular drift eliminators are effective up to 220 m/min (720 ft/min), which is more than adequate for most commercial towers. Because the drift requirements are more stringent, a different type of eliminator system is used, with a very delicate balance design and performance. If one or two eliminator blades are out of position, drift occurs quite readily. Several manufacturers have developed cellular eliminators to overcome the problem. Here again, the lower resistance of these new eliminators, plus their drift elimination effectiveness, make them a desirable conversion from the less efficient wood.

Retrofitting of an Ammonia Plant. Output of anhydrous ammonia was to be increased from 120 000 to 225 000 t/a. The cooling tower structure, fabricated of old-growth clear-heart redwood, was about 25 years old. It contained eight cells, each with a 6.1-m (20-ft) diameter fan driven by a 56-kW (75-hp) motor. It was designed to cool 136 m^3 of water per minute, entering at 46 °C and leaving at 29.4 °C, with a wet-bulb temperature of 25.5 °C. This produced a 17 °C (30 °F) cooling range with a 4 °C (7 °F) approach.

Because the tower was overdesigned initially, doubling anhydrous ammonia output required that cooling-water circulation be increased only to 161.25 m^3/min.

Addition of a ninth cell was strongly recommended (crossflow configuration, 7.5-kW fan). However, the project engineer decided to investigate the matter more closely. An inspection revealed that the tower's structure, connectors, and mechanical equipment were in excellent condition. Thermal calculations indicated that, with the installation of 0.61 m of cellular fill at the bottom of the tower, the existing eight cells could, with no additional horsepower, easily cool 161.25 m^3 of water per minute.

Furthermore, the new fill could be installed so as to allow more fill to be added at a later date to again upgrade the tower's capacity. To improve water distribution, the 25-year-old spray-nozzle system was replaced by nonclogging ABS nozzles. Because the original polystyrene fill was in relatively good condition, it was not removed. Instead, the existing wet-decking fill was augmented by the addition of a 0.61-m layer of high-efficiency PVC film fill.

Savings from rebuilding the existing eight cells instead of adding a new cell amounted to ca. $ 100 000. However, of greater significance were the ongoing savings resulting from the fact that 75 kW (100 hp) was not required to operate a ninth cell. With electricity at 7¢/kW h, operating a fan motor for 8760 h would cost $ 55 869 annually. Over the projected ten-year life of the tower, if estimated escalations in the cost of utilities are considered, more than $ 1×10^6 in operating expense would be saved. Thus, upgrading the tower was clearly more economical than adding to it [9].

Maintenance. Like any other piece of mechanical equipment, a cooling tower requires maintenance to be productive. Over the years, the elements do deteriorate. They should be inspected periodically – at least every two years – by a qualified cooling tower specialist, who will analyze the thermal operation as well as the mechanical, structural, and physical condition of the tower. In a written report, recommendations will then be made for repair and rebuilding specifications, together with an estimate of their cost.

Economic Aspects. Cooling towers producing colder water earn money for a facility by keeping head pressures and temperatures of compressors low, yielding more condensate product by the use of colder condensing temperatures off the tower, and reducing the electric penalty of generating equipment. The cooling tower, while appearing to be a simple box, is an important mechanism in the refrigeration chain, chemical plant process operation, and electric generating facility. It demands professional maintenance and operational understanding, to maximize its usefulness and profit-making potential.

5. Other Evaporative Cooling Devices

Natural-draft cooling towers have been a familiar sight in Europe for many years since they were first developed in Germany. Modern natural-draft towers are generally constructed of reinforced concrete. The shape of the tower has changed over the years. Early towers were cylindrical; later, a design using two truncated cones was employed. The current shape is hyperbolic, giving the tower superior strength and an ability to match the natural flow of air through the tower shell.

Natural-draft towers do not use fans to move the air: the flow of air through the tower is created by the density difference between atmospheric air and air inside the tower, which is warmed as the water is cooled. Hence, the tower is little more than a chimney that draws cool air in at the base and exhausts warm air at the top. The natural-draft tower is employed when a large

quantity of water, from 380 to >1320 m^3/min (100 000 to >350 000 gpm), must be cooled in a small space.

The drawback of the natural-draft cooling tower is that the approach to the wet bulb is ca. 8 °C (13 – 15 °F). Mechanical-draft towers can reduce the approach to 4.5 °C (7 – 9 °F), which is more desirable from an economic view point.

A modern development of the large concrete shell tower is a truncated cylinder ca. 18.3 m (60 ft) high, usually with eight cells of 9.15-m (30-ft) diameter fans and 200-hp motors. In the United States, few plans exist for building these natural-draft giants (100 – 150 m (300 – 500 ft) diameter and height) because of the efficiency and low-temperature water provided by mechanical-draft concrete towers.

Cooling ponds are rarely used these days because they require a large expanse of water. The cost of real estate makes this prohibitive. Also, in the United States, environmentalists protest when water from cooling towers is discharged into lakes, ponds, and streams, because it raises the temperature of the water and is apparently detrimental to aquatic life.

1. Introduction

A gaseous, liquid, or solid substance may be heated by direct contact between the substance and a heat carrier. This process is called direct heating. The physical state of the heat carrier is of secondary importance; however, industrial processes generally use gaseous or granular solid heat carriers. Liquid heat carriers are limited by the narrow range between their melting and boiling points. For this reason they have found no major application to date.

Heat transfer is usually a cyclic process: after the heat has been transferred, the heat carrier is purified of any gases, vapors, or solids that may have been taken up in the course of the process, is then reheated, and finally recycled to the process.

2. Direct Heating with Circulating Gas

The circulating gas flows through the substance to be heated. Mass transfer may take place during this process. This form of direct heating is especially effective for lumpy or granular solids. Below the range 500 – 600 °C, heat transfer is achieved almost exclusively by convection; above the range 800 – 900 °C, radiation becomes significant, although this is affected by the contents of water vapor and carbon dioxide in the circulating gas. Above 900 °C, radiation becomes even more important as the temperature is increased.

The heat carrier flow may be cocurrent, countercurrent, or cross-current in respect to the substance to be heated. Cocurrent flow permits high initial heat carrier temperatures and avoids an excessive final temperature of the substance. For the same heat-flux density, countercurrent flow gives lower local temperature differences, and the product is heated to its final temperature more gently. Countercurrent heating is thermally more efficient than cocurrent heating because the temperature of the substance to be heated can be raised above the temperature of the exiting heat carrier. Cross-current heating is used less frequently than the other two possibilities; however, it is used occasionally, e.g., in the case of a travelling grate heater.

The term quasi-cocurrent flow is used to describe heat transfer in a fluidized bed. The good heat exchange results in an almost uniform bed temperature, the gas and the solid leaving nearly with the same temperature. The unfavorable course of the temperature difference between the circulating gas and the solid to be heated is a significant drawback to an otherwise advantageous process.

The composition of the circulating gas depends on the temperature range. At low temperature, air is generally used, while gases containing little or no oxygen–frequently combustion gases–are used at high temperatures. Often the gases or vapors released upon heating the substance, most often steam, are used as the heat carrier.

The simplest method of heating the circulating gas is to mix it with hot combustion gas. The furnace fuel may be coal, oil, or gas–depending on the material to be heated and on the possibility of corrosion, odor, etc., caused by the presence of oxygen, sulfur, tar vapors, and solids in the circulating gas. Oil and gas are ideal fuels in this respect as they are easy to control. If combustion gas cannot be allowed to come into contact with the substance to be heated or if the gases or vapors released from the heated substance should not be mixed with combustion gases, the circu-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.b03_18

lating gas is heated indirectly in heat exchangers or heated directly by solids circulating in a second heat carrier loop.

A part of the circulating gas is continuously removed after each cycle to offset the amount of combustion gas added and the amount of gases and vapor released from the substance heated. Often, valuable byproducts can be separated by condensation from part or all of the circulating gas and withdrawn in liquid form. If dust is present, dust separators are used before the gas is cooled.

Applications. Circulating gases can be used in a number of ways to heat solids directly.

1) Gentle drying of substances to quickly remove vapors generated and to prevent sweating. Example: food drying with air recycle.
2) Cocurrent drying of substances in an entrained stream with hot flue gases containing little oxygen where the flue gas temperature is above the ignition temperature of the substance. Examples: flash dryer for coal (Babcock BSH), mill dryer for coal (Lurgi).
3) Steam drying of substances that are extremely sensitive to oxygen or that release hydrocarbons in addition to water vapor during drying. The hydrocarbons are recovered by partial condensation of the steam. Examples: rotary kiln steam drying of coal (Ahlsfelder Eisenwerke), steam flash drying of tar sands and oil-containing diatomaceous earth (Lurgi).
4) Carbonization/retorting of lumpy coal and oil shale. Example: Lurgi *Spülgas* retort, Unocal oil shale retort.

3. Direct Heating with Circulating Solid

3.1. Fundamentals

Frequently, a fine-granular solid is used as the heat carrier for thermal upgrading of solid, liquid, or gaseous fuels (retorting, coking, cracking) in which the emphasis is on the production of liquid and/or gaseous hydrocarbons. This process offers a number of advantages:

1) The vapors formed can be recovered undiluted by heat-carrier gases.
2) Cooling and condensation of the products is more economical because of the absence of heat-carrier gases.
3) The required heat-carrier volume is much smaller because the heat capacity per volume of solid is much greater than that per volume of gas.
4) Extremely short reaction times are achieved in the retorting of solid fuels such as coal, oil shale, or tar sands due to the high heat-transfer rates obtained by mixing the fine-grained heat carrier with the fine-grained feedstock. This normally leads to high yields of liquid hydrocarbons, and to relatively small reactor volumes.

A disadvantage of solid heat carriers is that their circulation system is generally more expensive than that for gases. In most cases, the solid reaction residue, the coke, spent shale, or spent sand is used as solid heat carrier. If the heat carrier is also to have a catalytic effect, then fine granular catalysts may be used as the heat carriers. Non-process-derived heat carriers without catalytic effect are of minor importance.

The coke contained in or deposited on the solid heat carrier is normally burnt with air at a controlled rate in a fluidized–or entrained–bed system. If the coke alone is not sufficient for reheating, a solid, liquid, or gaseous fuel must be added. Fluidized beds, mixers, and rotary kilns are used as reactors.

A temperature of ca. 1000 °C has been found to be the upper limit for the temperature of the solid heat carrier. The presence of small amounts of low-melting substances, e.g., salts, in the heat carrier, the substance to be heated, or the fuel may cause adhesion or sintering, which hinders recirculation.

In addition, processes recycling fine granular heat carriers have proved useful at lower temperatures because of their technological advantages. A disadvantage, however, is the necessity of equipment to remove the dust from the reaction and combustion gases. Other disadvantages include the abrasion of the internal lining of the circulation system and the loss of heat carrier due to abrasion. Because of the high investment costs such processes are generally economical only for large units. A schematic drawing of a

circulating solid heat carrier system is shown in Figure 1.

Figure 1. Lurgi – Ruhrgas process (LR process)

The fine-grained heat carrier is heated by burning its carbon content with air in a vertical lift pipe that simultaneously conveys it upward. The heat carrier is then separated from the combustion gases in a collecting bin and fed into the reactor at a controlled rate. After heat transfer, the cooled, coke-laden heat carrier is recycled to the lift pipe and reheated (regenerated), thus closing the loop. Heating and regeneration may also be carried out in a fluidized bed. In this case, however, an additional pneumatic transport device is required for the heat carrier.

Heat exchange between the hot gas and the solid heat carrier in the reactor may take place either in a countercurrent flow (when the solids travel through the reaction zone in a moving bed) or a quasi-cocurrent flow (when the solids are fluidized). For fine-granular materials, a fluidized bed or mixer is preferred as the reactor, primarily because of the favorable heat exchange between the reagent and the solid heat carrier. In addition, the throughput per unit cross section of the reactor reaches its optimum for a mixer. Another conceivable system is heat exchange between gas and a free-falling solid.

Numerous investigations [1–8] of heat and mass transfer between a gas and particle surfaces in a packed bed are available for various particle geometries. Empirical equations were derived for specific boundary conditions. The most comprehensive presentation was that of Jaeschke [9], who investigated packed beds with a broad range of void volumes and a variety of geometric forms. He presented his results in the form of a working diagram. His most important results are that transfer behavior depends strongly on the average specific void volume and on the effective flow velocity prevailing in the average void cross section.

For a bed made up of spheres with a specific void volume of ca. 0.4, the exchange is significantly greater than for a single sphere, under otherwise comparable conditions. The difference in transfer coefficients decreases with increasing void volume, becoming negligible for void volumes above 0.95.

For a fluidized bed, the average void volume depends primarily on the flow velocity. Jaeschke's results for particle beds of various degrees of loosening allow a comparison of convective transfer between nonfluidized and fluidized beds. According to Mosberger [10], along with the results of others [11, 12], there is no difference between a nonfluidized and a fluidized bed with respect to heat- and mass-transfer coefficients [13], for identical average void ratios under comparable conditions. Neither the intrinsic movement of the particles nor the frequently observed bumps and bubbles in a fluidized bed have a distinctly recognizable effect on heat and mass transfer. This is true for spherical and cubic particles with diameters between 0.7 and 9 mm. In fluidized beds of significantly smaller particles, different flow conditions, such as channelling, can be expected. In addition, an exact determination of particle surfaces becomes problematic. If heat- and mass-transfer values are known, then the residence time of the solid in the reactor, and thus the bed height, may be calculated. The reactor cross section is calculated from the gas flow rate and the permissible gas velocity.

If heating the reagent causes it to undergo a significant endothermal or exothermal reaction,

then bench-scale tests should be made to obtain information on the necessary solids flow rate.

The most favorable grain size, varying from fine dust to particles with 5-mm diameter, depends on the process conditions. Diameters between 0.1 and 3 mm are generally preferred. The void volume should be between 36 and 40 % for packed beds and between 50 and 80 % for fluidized beds. During operation, the particles assume a near spherical shape as a result of abrasion.

The number of spheres or exchange surface for arbitrary void ratios ε ($0 < \varepsilon < 1$) may be obtained by multiplication of the figures in Table 1 by the factor

$$\frac{1-\varepsilon}{0.6}$$

Owing to the large surface of granular solids (see Table 1) and to the favorable heat- and mass-transfer coefficients of packed and fluidized beds, the reaction volume required is relatively small. The effective gas veloctiy in moving bed reactors is smaller than the fluidizing threshold, whereas in fluidized beds, it is two- to sixfold greater.

Table 1. Number of spheres and heat-exchange surface per cubic meter of bed material as a function of sphere diameter for a void ratio $\varepsilon = 0.4$

	Spherical diameter, mm			
	1	2	5	10
Number of spheres, 10^6 m^{-3}	1147	143	9.17	1.15
Heat exchange surface, m^{-1}	3600	1800	720	360

Heat transfer between fine-grained solids in a mixed bed has been investigated relatively little. Available conclusions [14, 15] are that heat transfer from one fine-grained solid to another depends heavily on the avarage particle size and the mixing quality of the reactor. Nearly complete heat transfer in fluidized beds and mechanical agitators with average particle diameters of 0.5 – 1 mm is reached within seconds. In such systems heat is transferred partly by direct grain-to-grain contact, partly by convection of the gas in the void, and partly by radiation from solids and gases.

Theoretical evaluation is difficult because all these processes are mutually superposed. Most investigations involving fine-grained solids are empirical; however, they are generally adequate for practical purposes.

A solid heat-carrier should have the following properties:

1) High specific heat, to keep the circulating mass small
2) Good compressive strength at high temperatures
3) Low abrasive wear, even in the case of sharp temperature changes
4) Low abrasive action on the refractory linings
5) High thermal conductivity
6) Chemical resistance to the combustion gases and the substances to be heated
7) Catalytic action in special cases

The residence time of the solid in the regenerator and reactor may be only a few seconds when fine grained solids are used. Stability of the solids to thermal shock is of crucial importance in this case.

3.2. Applications

The fundamentals of heat transfer by means of circulating granular solids or "hot stones" was reported in German publications as early as 1927 [16–18]. The fluid coking process developed by Exxon for heavy oils or residual oils uses a fluidized bed of hot, fine-grained petroleum coke into which the oil is injected. In a second fluidized bed, the circulated coke is regenerated and reheated by partial combustion with air. The petroleum coke itself is formed in the first fluidized bed as a coking residue [19, 20]. Around 1940, heat transfer by circulating solids was introduced in the USA for the catalytic cracking of crude oils [21, 22]. In this case, the solid heat carrier is a catalyst.

The LR process for retoring fine granular coal was developed by Lurgi and Ruhrgas around 1950. It uses a mixer – reactor in which the feed material is intimately mixed with hot, circulated coke and retorted (devolatilized) within a few seconds [23–25]. The coke is then reheated in a pneumatic lift pipe by partial combustion with air as the coke is conveyed upwards into the collecting bin. In the collecting bin, it is separated from the combustion gases and returned to the mixer – reactor.

Since then, the LR process has also been used to produce olefins from various crude oil fractions with sand as the heat carrier (sand cracker) to retort oil shale and tar sand, and to coke residue oils (asphaltenes, hydrogenation residues, etc.)

1. Refrigeration [1–3], [28], [32], [34]

The technology of generating and using subambient temperatures is divided into three fields: refrigeration, low-temperature technology, and cryogenics. The boundaries between these fields are not clear cut. *Refrigeration* is generally understood to mean from ambient temperature down to the standard boiling point of ethylene (ca. 170 K); *low-temperature technology* is from 170 K down to the melting point of nitrogen (63 K); and *cryogenics* is below 120 K, as suggested by the Ausschuss für Tieftemperatur-Terminologie (Committee for Low-Temperature Terminology). This article deals with refrigeration; cryogenics is the subject of a separate article (→ Cryogenic Technology).

The purpose of refrigeration technology is to cool materials to subambient temperatures or hold them at such temperatures. The substance to be refrigerated is cooled by a working fluid, which moves in a closed cycle. Most of the cyclical processes employed for refrigeration are reversals of processes used in heat engines.

In *cold-gas processes*, the working fluid is always in the gaseous state; in *cold-vapor processes*, the working fluid changes state from liquid to gas and back to liquid. Cold-gas processes are energetically less favorable than cold-vapor processes at all temperatures of interest for refrigeration, i.e., down to ca. − 100 °C. In practice, cold-gas machines are important at lower temperatures, and these systems are therefore discussed under → Cryogenic Technology.

Cold-vapor systems use the latent heat of evaporation of a liquefied working fluid in a closed cycle to generate cold. The fluid (refrigerant) moves continuously through the cycle. The evaporating refrigerant remains at either constant pressure or constant temperature as heat is absorbed from the medium being cooled; it is then condensed at a higher pressure. The condensing pressure is dictated by the conditions of heat rejection to the surroundings and by the vapor pressure of the refrigerant. To keep the refrigerant circulating between the two pressures, energy must be supplied to the system in the form of mechanical work or heat.

Cold-vapor machines include the following types:

1) compressor refrigerating systems,
2) absorption refrigerating systems, and
3) steam-jet refrigerating systems.

Mechanical or electrical energy must be used to drive compressor refrigerating machines; absorption and steam-jet refrigerating systems are powered by thermal energy.

1.1. Compressor Refrigerating Systems [2], [3], [14], [17], [19], [20], [28], [35–43]

The most frequently used class of cold-vapor refrigeration machines is the compressor type. Figure 1 is a schematic diagram of a single-stage refrigeration system.

Figure 1. Single-stage compressor refrigerating system
a) Compressor; b) Condenser; c) Expansion valve; d) Evaporator; e) Compressor drive motor

A refrigerant enters the suction of a compressor (a) at a low pressure p_0, it is compressed to

a higher pressure p_c, and is then condensed in a condenser (b) by rejection of heat to the surroundings. The liquefied refrigerant is expanded to pressure p_0 in an expansion valve (c). The amount of refrigerant vapor (flash gas) produced depends on operating conditions; this part of the refrigerant cannot be used to generate cold. As it absorbs heat, the liquid refrigerant evaporates in the evaporator (d); it then returns to the suction of the compressor.

Figure 2. Diagram of the single-stage process in a compressor refrigerating system (temperature vs. specific entropy)
1 – 2 = Isentropic compression; 2 – 3 = Cooling and condensing at constant pressure; 3 – 4 = Expansion (isenthalpic); 4 – 1 = Evaporation at constant pressure; 1 – 2 – 3 – 4 – 1 = Specific work of compression; 1 – 4 – 5 – 6 – 1 = Specific refrigerating effect

Figure 3. Diagram of the single-stage compressor refrigerating process (log pressure vs. specific enthalpy)
1 – 2 = Isentropic compression; 2 – 3 = Cooling and condensing at constant pressure; 3 – 4 = Expansion (isenthalpic); 4 – 1 = Evaporation at constant pressure

The thermal balance of the process is then

$$\dot{Q}_0 + P = \dot{Q}_c$$

where $\dot{Q}_0$ is the rate of cold production (refrigerating effect) in the evaporator, P is the compressor drive power, and $\dot{Q}_c$ is the rate of energy rejection in the condenser. When referred to the mass flow rate, this relation is

$$q_0 + w = q_c$$

where w is the specific work of compression. For energetic assessment of compressor refrigerating systems, the coefficient of performance (ε) is generally used; this is the ratio of refrigerating effect $\dot{Q}_0$ to the electrical or mechanical power supplied P:

$$\varepsilon = \frac{\dot{Q}_0}{P} = \frac{q_0}{w}$$

The coefficient of performance can be determined both for the real refrigeration process and for a suitable ideal (theoretical) reference process. The ratio of the coefficients of performance of these processes is called the efficiency factor (η):

$$\eta = \frac{\varepsilon}{\varepsilon_t}$$

For the fundamental ideal reference process in refrigeration, the Carnot process running between the absolute condensing temperature T_c and the absolute evaporating temperature T_0, the coefficient of performance is

$$\varepsilon_c = \frac{T_0}{T_c - T_0}$$

The smaller the temperature difference ($T_c - T_0$), the higher is the coefficient of performance.

The ideal process for a compressor refrigerating system is described by the temperature – entropy ($T - s$) diagram (Fig. 2), which shows the specific refrigerating effect q_0 and the specific compressor work w as separate areas. A log pressure vs. enthalpy diagram ($p - h$ or Mollier diagram, Fig. 3) is more useful because (1) both specific quantities are defined as enthalpy differences, (2) the process runs between two fixed pressures, and (3) expansion is a constant-enthalpy process. The quantities, now referred to 1 kg of circulating refrigerant, can be plotted as lengths. The specific compression work (w),

the specific refrigerating effect (q_0), and the specific thermal power (q_c) are defined as follows:

$$w = h_2 - h_1$$

$$q_0 = h_1 - h_4$$

$$q_c = h_2 - h_3$$

where the numerical subscripts refer to the points shown in Figure 3.

Performance Figures. The mass flow rate of refrigerant for a given refrigerating effect $\dot{Q}_0$ is

$$\dot{m}_R = \frac{\dot{Q}_0}{q_0} = \frac{\dot{Q}_0}{h_1 - h_4}$$

The specific refrigerating effect per unit specific volume q_{0v} is given by

$$q_{0v} = \frac{h_1 - h_4}{v_1}$$

where v_1 is the specific volume of refrigerant vapor at the suction. The volume flow rate at the suction of the compressor is thus

$$\dot{V}_1 = \frac{\dot{Q}_0}{q_{0v}} = \frac{\dot{Q}_0}{h_1 - h_4} v_1 = \dot{m}_R v_1$$

The coefficient of performance ε_t of the ideal process is

$$\varepsilon_t = \frac{q_0}{w} = \frac{h_1 - h_4}{h_2 - h_1}$$

The power consumption of the ideal process for a given refrigerating effect can be determined:

$$P_t = \frac{\dot{Q}_0}{\varepsilon_t} = \dot{Q}_0 \frac{h_2 - h_1}{h_1 - h_4}$$

The necessary rate of heat rejection needed in the condenser for the ideal process is

$$\dot{Q}_{ct} = \dot{m}_R q_{ct} = \dot{m}_R (h_2 - h_3)$$

In practice, compression is not an isentropic process, but a polytropic one in which the entropy increases. This nonideal behavior is described by the indicated efficiency η_i of the compressor used. The indicated power consumption P_i for a refrigerating effect $\dot{Q}_0$ is thus

$$P_i = \frac{P_t}{\eta_i} = \frac{\dot{Q}_0}{\varepsilon_t \eta_i}$$

When frictional losses in the compressor are taken into account, the effective power consumption P_e is

$$P_e = \frac{P_t}{\eta_e} = \frac{\dot{Q}_0}{\varepsilon_t \eta_e}$$

Figure 4. Single-stage compressor refrigerating system with internal heat exchange
a) Compressor; b) Condenser; c) Evaporator; d) Expansion valve; e) Heat exchanger; f) Compressor drive motor

Subcooling. The liquefied refrigerant can be subcooled by heat exchange with the cold vapor from the evaporator. A system with a heat exchanger provided for this purpose is depicted in Figure 4.

Subcooling the refrigerant results in a gain in specific refrigerating effect. The increase for some halocarbon refrigerants is greater than the increase in specific compressor work because compression is started in the superheating region instead of at saturation. The process is described by the $p-h$ diagram in Figure 5. This heat-exchange step can also be used to prevent liquid droplets from being entrained from the evaporator into the compressor. Valve damage in reciprocating compressors can thus be avoided.

Figure 5. Diagram of the compressor refrigerating process with internal heat exchange (log pressure vs. specific enthalpy)
$h_{1'} - h_1 = h_3 - h_{3'}$

Figure 6. Two-stage compound compressor refrigerating process with two-stage expansion
a) High-stage compressor; b) Condenser; c) Intermediate-pressure vessel; d) Evaporator; e) Low-stage compressor; f) Expansion valve; g) Compressor drive motor

Compound Compression. In positive-displacement compressors, the volumetric and the indicated efficiencies of the compressor fall off sharply at higher compression ratios. In addition, compression temperatures may reach excessive values if the ratio is high. This happens at evaporating temperatures between ca. -20 and $-45\,^{\circ}$C, depending on the condensing temperature, the refrigerant, and the compressor design. In order to avoid these problems, compound (two-stage and multistage) compression systems are used. The optimum intermediate pressure for two-stage compression is

$$p_{\mathrm{I}} = (p_{\mathrm{c}} \cdot p_0)^{1/2}$$

Two-Stage Expansion. The refrigerating effect declines as the compression ratio increases, because of the high vapor content in single-stage expansion. Performance can be greatly improved by expansion in two stages. Figure 6 shows a process with two-stage compression and two-stage expansion; this arrangement is common in larger refrigerating systems that use ammonia as the refrigerant. Figure 7 is the corresponding $p-h$ diagram for this process.

Figure 7. Diagram of compressor refrigerating process with two-stage compression and two-stage expansion (log pressure vs. specific enthalpy)

The low-stage compressor (Fig. 6, e) takes vapor from the evaporator (d) and compresses it to the intermediate pressure. This vapor goes to the intermediate-pressure tank (c), where it is cooled to saturation by refrigerant that has been expanded to the intermediate pressure. All the vapor passes to the suction of the high-stage compressor (a), where it is compressed and then condensed in the condenser (b). An expansion valve (f_1) allows the condensate to expand to the pressure prevailing in the intermediate-pressure tank; further expansion to the evaporating pressure takes place in a second expansion valve (f_2). The vapor produced by heat exchange in

the intermediate-pressure tank, along with the vapor from expansion, results in the mass flow rate of refrigerant being greater in the high-pressure part of the system than in the low-pressure part.

Two-Stage Compression with Two Evaporators. If additional refrigeration is necessary at the temperature corresponding to the intermediate pressure, another evaporator can be placed in parallel with the intermediate-pressure tank. Figure 8 shows such a system with one evaporator for low pressure (e) and one for intermediate pressure (d). The additional cooling of the vapor compressed by the low-stage compressor reduces energy consumption. The power balance for this two-stage process is as follows:

$$\dot{Q}_c = \dot{Q}_{0LP} + \dot{Q}_{0IP} + P_{LP} + P_{HP} + \dot{Q}_i$$

where $\dot{Q}_c$ is the rate of heat rejection in the condenser, $\dot{Q}_{0LP}$ is the refrigerating effect in the evaporator at p_0, $\dot{Q}_{0IP}$ is the refrigerating effect in the evaporator at p_I, P_{LP} is the drive power of the low-stage compressor, P_{HP} is the drive power of the high-stage compressor, and $\dot{Q}_i$ is the rate of heat rejection in the intercooler.

Figure 8. Two-stage compound compressor refrigerating system with two evaporators at different temperatures and with interstage cooling by cooling water and refrigerant

The refrigerant mass flow rates, the suction volume flow rates, and the effective power consumptions for the compressors can be determined from information provided on the single-stage process.

Two-Stage Compression with Single-Stage Expansion. On grounds of design simplicity, two-stage expansion is often not used in small systems with two-stage compression. This process is depicted in Figures 9 (schematic diagram) and 10 ($p-h$ diagram). In the low-pressure stage, the vapor is compressed from pressure p_0 to the intermediate pressure p_I. The vapor is then cooled by refrigerant from the condenser, which is injected through an expansion valve.

Figure 12. Diagram of the process illustrated in Figure 11 (log pressure vs. specific enthalpy)

When *halocarbon refrigerants* are employed, the system shown in Figures 11 (schematic) and 12 ($p-h$ diagram) is often used. Before expansion at low pressure, the refrigerant is subcooled almost to the saturation temperature corresponding to the intermediate pressure. Subcooling is accomplished by part of the refrigerant flow evaporating at the intermediate pressure. Energetically, the process is almost equivalent to two-stage expansion; it offers some advantages with regard to control of the refrigerant mass flow rate in the low-pressure section.

Cascade Compressor Refrigerating Systems. At evaporating temperatures between −70 and −110 °C, the large difference between the evaporating and compressing pressures has unfavorable effects. Depending on the refrigerant, the pressure on the condenser side may be excessively high or may exceed the critical pressure. On the low-pressure side, the pressure can be so low that entry of air into the system becomes a danger. The use of a given refrigerant may by ruled out by its freezing point and by the high specific volume of the suction vapor at low temperatures. The process is, therefore, divided into two separate loops and a suitable refrigerant is chosen in each loop for the pressures occurring there. Figure 13 shows a simple cascade system with two loops.

Figure 13. Cascade compressor refrigerating system
a) Compressor; b) Cascade cooler; c) Evaporator; d) Expansion valves; e) Condenser; f) Compressor drive motor

The refrigerant in the low-temperature circuit is condensed by evaporating high-temperature circuit refrigerant in the cascade cooler; i.e., the refrigerating effect of the high-temperature circuit is used to remove heat of condensation from the low-temperature circuit. In this way, only the evaporator with the lowest evaporating temperature generates the useful refrigerating effect. Depending on the compression ratios in the circuits of the cascade system, the refrigerant can be compressed in several stages.

1.1.1. Refrigerants for Compressor Refrigerating Systems [4], [14], [22], [28], [44–47]

The working fluids moving in a closed cycle in compressor refrigerating systems must satisfy many requirements. These requirements are primarily concerned with thermodynamic properties, heat-transfer characteristics, chemical and physiological behavior, and usability with various compressor designs.

A refrigerant must have good chemical stability under working conditions and in the presence of construction materials and lubricants. Its pressure must not be too high, but it should not be lower than atmospheric pressure at standard temperature and, if possible, in the evaporator. Other characteristics of a good refrigerant are low compression ratio (the ratio of the condenser pressure p_c to the evaporator pressure p_0, corresponding to the condensing temperature t_c and the evaporating temperature t_0), high specific enthalpy of evaporation, and small isentropic exponent (see Table 1). Furthermore, the volumetric refrigerating effect (the refrigerating effect per unit refrigerant volume flow rate at the suction) is a crucial factor; it depends on both the specific volume of the vapor and the specific enthalpy of evaporation.

The two main types of refrigerants are ammonia and chlorofluoro derivatives of methane and ethane (halocarbon refrigerants). Pure hydrocarbons are also used in petrochemical plants.

Ammonia has very good thermodynamic properties, but is toxic and flammable (→ Ammonia, Chap. 8.). Because it also attacks materials containing copper, it is unsuitable for sealed refrigeration compressors, where the winding of the drive motor comes in contact with the refrigerant. The use of ammonia is virtually restricted to large-capacity industrial refrigeration systems.

In contrast, *halocarbon refrigerants* are neither toxic nor flammable (→ Chlorinated Hydrocarbons, → Fluorine Compounds, Organic, Chap. 3.; → Bromine Compounds). They are employed in nearly all types of compressor refrigerating systems, from home refrigerators to large air-conditioning plants. However, some halocarbon refrigerants have harmful environmental effects, especially on the ozone layer.

Refrigerant nomenclature is standardized. Each name consists of the letter R (for refrigerant) and a multidigit number from which the chemical composition can be determined (→ Fluorine Compounds, Organic, Chap. 3.).

Table 1 gives some characteristic *thermodynamic data* for the most important refrigerants. For chlorotrifluoromethane, ethane, and ethylene, the last column gives the volumetric refrigerating effect at a condensing temperature of −30 °C and an evaporating temperature of −80 °C, because these substances are primarily low-temperature refrigerants for cascade systems. Table 2 gives the temperature ranges and applications for the refrigerants listed in Table 1.

Detailed vapor tables, $p-h$ diagrams, and equations of state for use on computers are available for designing refrigeration processes. Table 3 gives a selection of data from the vapor tables for the two most important refrigerants, ammonia and chlorodifluoromethane. Along with temperature and pressure, the table includes the specific volume (v) and specific enthalpy (h) of the liquids and saturated vapors.

Special requirements (purity, water content, and contents of gaseous impurities, acids, or residues after evaporation) for several halocarbon refrigerants are specified in DIN standards. With regard to the pressures occurring in the refrigerant loop, the operating and test pressures for system components are dictated by the refrigerant used. To ensure that no refrigerant escapes to the environment, leak tests are performed before a refrigeration system is placed in service. The most important safety principles for refrigerating systems are given in ISO 1662.

1.1.2. Compressors [5], [17], [30], [48–65]

Two kinds of machines are used to compress the refrigerant vapor:

1) Displacement machines (reciprocating, screw, multi-vane-rotary compressors)
2) Dynamic machines (centrifugal or turbine compressors)

The crucial difference in the operating properties of these two types is that the volume flow rate (gas flow) is highly dependent on the compression ratio in dynamic machines, whereas it

∗ p = pressure; v' = specific volume of the liquid; v'' = specific volume of the saturated vapor; h' = specific enthalpy of the liquid; h'' = specific enthalpy of the saturated vapor.

is virtually constant in positive-displacement devices. Figure 14 shows the characteristics of both types of machine.

Figure 14. Operating curves for dynamic and positive-displacement compressors
a) Operating point; b) Dynamic compressor; c) Positive-displacement compressor

The gas flow and thus the refrigerating capacity are crucial in the selection of compression equipment. In Figure 15 the ranges of application of the most important compressor types are plotted as a function of the refrigerating capacity and evaporating temperature for a condensing temperature of 35 °C.

Figure 15. Range of application for refrigerant compressors
a) Centrifugal compressors; b) Screw compressors; c) Reciprocating compressors

1.1.2.1. Displacement Compressors

Reciprocating Compressors. *Piston-type reciprocating compressors* are used almost without exception for low and moderate capacities, conventional refrigerants, and evaporating temperatures of ca. − 60 °C.

These compressors are multicylinder machines (2 to 16 cylinders) with an inline-, V-, or W-configuration. The flow of refrigerant vapor alternates in direction, i.e., the cylinder head contains suction and discharge valves in an arrangement that causes the flow direction to reverse. These working valves are usually ring-plate or lamellar valves. Piston compressors operate at speeds between 700 and 1500 rpm, depending on size. The mean piston speed is ca. 4.0 m/s. In order to prevent wear of the cylinder contact surfaces and undue loading of the working valves, this figure should not be greatly exceeded. For compressors with gas flows $< 20\,m^3/h$, rotation speeds up to 3000 rpm are common. Piston compressors are usually driven by electric motors with either direct coupling or belt drives. For halocarbon refrigerants and capacities up to ca. 300 kW, the direct-coupled drive motor is often mounted in a housing with the compressor (hermetic refrigeration compressor) and cooled by the refrigerant vapor on the suction side. Advantages of this design include diminished leakage, space and weight savings, reduced noise, and lower maintenance costs.

For low evaporating temperatures (t_0 between − 20 and −45 °C), *multistage compressors* are employed. The stage compression ratios are dictated by the number of cylinders in the individual stages. Multistage compression can also be achieved by connecting two different-sized compressors in series.

Approaches used to match compressor output to varying cold requirements include not only speed control (change-pole motors) and throttling of the refrigerant vapor on the suction side, but also inclusion and exclusion (bypassing) of individual cylinders or groups of cylinders. In this type of control, compressed refrigerant vapor from the affected cylinders is returned to the suction side through pressure-reducing valves, or the suction-valve plates of individual cylinders are held open, usually by oil pressure. For simpler control, the capacity can also be divided among several smaller compressors, which are put on-line according to demand (interconnected refrigerating system).

The *volumetric losses* of a piston-type compressor are expressed in terms of the total volumetric efficiency λ, which is the ratio of the effective volumetric flow $\dot{V}_{v1}$ under suction conditions to the theoretical volumetric flow $\dot{V}_g$ calculated from the motor speed and the cylinder dis-

placement. The total volumetric efficiency declines as the compression ratio increases. It also depends on the refrigerant, the suction temperature, and the clearance volume:

$$\lambda = \frac{\dot{V}_{v1}}{\dot{V}_g} = \frac{\dot{m}_R v_{v1}}{\dot{V}_g}$$

where $\dot{m}_R$ is the mass flow rate of refrigerant and v_{v1} is the specific volume under suction conditions.

The nomograph of Figure 16 gives the total volumetric efficiency λ and the indicated efficiency η_i for compressors operating with ammonia as functions of the compression ratio p_c/p_0, evaporating temperature t_0, geometric stroke displacement per hour $\dot{V}_g$, and clearance volume ε_0. The nomograph is based on the relation

$$\lambda = \eta_v - (1 - \eta_w)$$

where η_v is the volumetric efficiency (i.e., the fraction of the reduction in delivery that is due to reexpansion of gas in the clearance volume and to valve resistance) and η_w is the wall efficiency. The wall efficiency allows for losses due to valve and piston leakage, as well as the decrease in suction-side gas density due to heating at the valves and the cylinder walls. The total volumetric efficiency found should be multiplied by a correction factor c for low suction temperatures when $t_0 < -25\,°C$. The correction factor is given by the following:

t_0, °C	−25	−30	−40	−50	−60	−70
c	1.0	0.95	0.90	0.85	0.80	0.75

The use of the nomograph is illustrated by a *sample calculation* (dashed lines in Figure 16):

Evaporating temperature $t_0 = -20\,°C$
Condensing temperature $t_c = +25\,°C$
Clearance volume $\varepsilon_0 = 0.04$; geometric displacement per hour $\dot{V}_g = 50\,m^3/h$
Compression ratio $p_c/p_0 = 5.3$
Volumetric efficiency $\eta_v = 0.82$
Wall losses $(1 - \eta_w) = 0.16$
Correction factor for all t_0 over $-25\,°C$, $c = 1$
Total volumetric efficiency $\lambda = [\eta_v - (1 - \eta_w)]$ $c = 0.66$; $\eta_i/\lambda = 1.18$
Indicated efficiency $\eta_i = 1.18 \times 0.66 = 0.78$

Figure 16. Total volumetric efficiency λ and indicated efficiency η_i of ammonia compressors (from DKV Specification 3-01)

The indicated power in terms of the indicated efficiency is given by

$$P_i = P_t/\eta_i$$

where P_t is the theoretical power consumption (see Section 1.1). The mechanical efficiency η_m must be included in the effective power consumption; this value is between 0.85 and 0.93 and depends on the displacement volume. For compressors operating on other refrigerants, this graphical representation gives usable values if the pressure drop in the working valves does not differ from that for ammonia.

Oil that enters the refrigerant loop in oil-lubricated piston compressors must be separated from the refrigerant stream before the inlet to the condenser, especially when no oil return from the evaporator is provided. This is necessary for plants using ammonia as refrigerant and for those using halocarbon refrigerants at lower evaporating temperatures. Gravity or inertial oil separators are installed for this purpose on the discharge side of the compressor. The separating efficiency can be enhanced by internal impingement collectors. Such oil separators ensure that an adequate quantity of oil is returned to the

compressor and that the lubricating oil will not degrade heat transfer in the heat exchangers.

In special cases, e.g., at very low evaporating temperatures, oil-less compression may be required. Nonlubricated compressors are used widely in process engineering and are suitable for this purpose. In these crosshead machines, either the piston does not make contact with the cylinder (labyrinth compressor) or the piston rings are made of a self-lubricating material, usually polytetrafluoroethylene or sintered carbon with appropriate additives (plastic-ring nonlubricated compressor).

Figure 17. Principle of a rotating-screw compressor
A) Cross section: a) Inlet; b) Female rotor; c) Male rotor; d) Return channel; e) Return channel; f) Movable slidingB) Top view of the rotors: a) Inlet; b) Discharge

Screw Compressors. Screw compressors are being used increasingly in industrial refrigeration systems, especially those with moderate and high capacity.

Most of these devices are oil-flooded, two-shaft machines (Fig. 17). The refrigerant vapor is compressed by two screw-shaped rotors (b and c), which engage and make contact with each other. The rotors turn in opposite directions inside a closefitting case. As the rotors turn, the spaces between teeth continuously increase and decrease in size because of the screw shape. Thus, as in a reciprocating compressor, refrigerant vapor is pulled in, compressed, and discharged. The position and size of the discharge port in the housing determine the ratio of discharge to suction volume (installed volume ratio or, because for a given refrigerant conversion to pressure is possible, installed pressure ratio).

The screw compressor has neither clearance volume nor working valves. Precooled oil is usually injected into the compression space between rotors after completion of the suction process. This procedure allows direct torque transmission from the driven rotor (usually male) to the partner rotor, seals the clearances between rotors and housing, and removes the enthalpy of compression. Oil injection is driven by a pump or by the pressure of liquefaction. Independent of the compression ratio, pressure differences up to 2 MPa can be attained without the compression temperature exceeding 100 °C. Injected oil is separated from the refrigerant stream in one or two oil separators (depending on the degree of separation required), which are connected in series. The oil is cooled and returned to the compressor. The principal refrigerants used are ammonia (R 717) and chlorodifluoromethane (R 22); in heat-pump service, dichlorodifluoromethane (R 12) and dichlorotetrafluoroethane (R 114) are also employed.

Capacity is controlled by altering the mass flow rate with an axially adjustable movable sliding. When the sliding is moved toward the discharge port, usually by oil pressure, it creates an opening through which the suction-side vapor flows back into the inlet casing. Efficiency factors are favorable over a wide range of part-load conditions.

Small screw compressors, without a movable sliding and offering theoretical flow rates $\leq 100\ m^3/h$, are available. As with smaller reciprocating compressors, capacity can be divided

among several machines, which are turned on and off to meet demand.

Besides the tooth shape and number shown for the male and female rotors in Figure 17, *other rotor profiles* with different numbers of teeth are also available. Energetically optimal rotor tip speeds are generally 25 – 35 m/s; with smaller rotors, gearboxes are required between drive motor and compressor in order to attain these values. The drive motor speed is usually $3000\,\mathrm{min}^{-1}$.

Semihermetic screw compressors are used, especially in air conditioning. In these devices, the refrigerant vapor on the suction or discharge side is used to cool the rotor.

The most important qualities of the screw-type compressor are simple, compact design; low vibration and noise levels; high reliability; insensitivity to liquid refrigerant flow rates on the suction side; efficient, continuous capacity control; and efficiency factors similar to those of reciprocating compressors.

To reduce the specific power consumption, medium- and high-capacity screw compressors are fitted with an intermediate injection device (see Section 1.1). To allow further optimization of the efficiency factor under a variety of service conditions, the installed volume ratio of some types can be varied continuously during operation.

Multivane Rotary Compressors. The multi-vane rotary compressor (Fig. 18) consists of a cylindrical housing (a) in which an eccentrically mounted rotor (c) with several vanes (b) rotates.

Figure 18. Principle of a multivane rotary compressor
a) Housing; b) Vane; c) Rotor

The vanes, guided in the rotor, are pressed by centrifugal force against the housing wall, forming a sequence of continuously varying compression spaces.

Overflow losses at the vanes limit compression ratios to only 1 : 5 for economic reasons. Therefore, multivane rotary compressors have restricted applications in refrigeration. They are used as boosters in reciprocating compressor plants with theoretical flow rates up to ca. $1000\,\mathrm{m}^3/\mathrm{h}$. Their advantages are low mass and small volume (due to the high rotation speeds) as well as vibration-free operation. Drawbacks include vane wear, especially when lubrication is inadequate, and the sharp drop in volumetrc efficiency at higher compression ratios.

1.1.2.2. Dynamic Compressors

Centrifugal Compressors. All turbine compressors (turbocompressors) for refrigeration service are radial-flow centrifugal designs; they are used for refrigerating capacities from ca. 300 to $>10^4$ kW. These machines have significant advantages over reciprocating compressors: low mass per unit capacity, decreased space requirement, vibration-free operation, oil-free compression, and high reliability due to the absence of reciprocating machine parts and valves.

For a given design, the discharge head Δh for one stage is set by the tip speed u of the gas:

$$\Delta h = \psi \frac{u^2}{2g}$$

where the pressure coefficient ψ depends on the vane shape (ψ = ca. 1.0 for vanes with a backward curve and 1.3 for vanes with radial ends). If the discharge head is known, then the compression ratio for isentropic compression is

$$\frac{p_c}{p_0} = \left(\frac{x-1}{x} \cdot \frac{\Delta h}{T_0} \cdot \frac{M_\mathrm{r}}{R} + 1\right)^{\frac{\varkappa}{\varkappa-1}}$$

where M_r is the relative molecular mass and R is the universal gas constant. Substances with high relative molecular masses thus favor the use of centrifugal compressors in terms of construction cost: achieving a given compression ratio then requires a lower discharge head, and often fewer stages, than with a low molecular mass fluid. Typical refrigerants for turbocompressor refrigeration plants are trichlorofluoromethane (R 11), dichlorodifluoromethane (R 12), and dichlorotetrafluoroethane (R 114); for very high

capacities, chlorodifluoromethane (R 22) and ammonia (R 717) are also candidates. Petrochemical refineries use ethylene (R 1150), propane (R 290), and propene (R 1270) as refrigerants.

Centrifugal compressors always offer lower compression ratios than positive-displacement machines. For an evaporating temperature of $-20\,°C$ and a condensing temperature of $+35\,°C$, the required compression ratio can be reached in a single stage with a reciprocating compressor; two stages of centrifugal compression are needed for R 22 and eight for R 717.

The main dimensions of centrifugal compressors are dictated not only by the refrigerant but also by the delivery volume and head. The delivery volume is proportional to nD^3b, and the head is proportional to n^2D^2 ; these relationships show how important the impeller outside diameter D is. Low delivery volumes allow small diameters, high rotation speeds n, and small impeller channel widths b. The minimum delivery volume is determined by frictional losses, which increase when the impeller channel width is small. In multistage compressors, often designed with equal-sized impellers, the suction-side volume of the last stage governs the minimum delivery volume.

The characteristic tip speed for the delivery head is limited by the strength of the impeller. For a medium with a relatively high molecular mass (low acoustic velocity), a further limit is that the mach number (ratio of flow velocity to acoustic velocity) at the inlet to the impeller must not exceed 0.8 – 0.9. Modern machines, with few exceptions, run at 4000 to 20 000 min^{-1}

Compressors are generally driven by electric motors provided with gearboxes; gas and steam turbines are also employed in larger units. For air conditioning, an enclosed construction is often used in which the electric motor is mounted in the housing and cooled by the refrigerant.

The operating characteristics of centrifugal compressors result from the heavy dependence of discharge volume on compression ratio and from the location of the pumping-limit curve. The pumping limit dictates the minimum quantities for various rotational speed curves; the speed must not go below this limit if unstable operation is to be avoided.

Capacity can be most economically controlled through the rotation speed, which is the usual arrangement with a turbine drive. If a constant-speed drive is employed, control by inlet guide vanes is also energetically favorable. A set of guide vanes ahead of the impeller imparts a twist to the inlet flow, thus altering the delivery head at constant rotation speed. A family of operating characteristics similar to those for speed control is obtained. This form of control is used in most motor-driven compressors.

Energetically unfavorable control techniques used to a limited extent include throttling the suction and varying the cooling-water rate. Pumping-limit control ensures that the flow under part-load conditions does not decrease below a level that makes operation unstable. If the flow corresponding to the desired refrigeration capacity is below the pumping limit, the difference flow rate must be additionally compressed. This quantity is usually returned by throttling (bypass control); expansion turbines are also used in large plants.

1.1.3. Condensers [3], [7], [15–17], [23], [27], [30], [33], [66–77]

Refrigerant exiting the compressor as a superheated vapor goes to the condenser, where it is cooled to the condensing temperature, liquefied, and subcooled to an extent that depends on equipment design and operating conditions. The heat rejected is usually absorbed by ambient air or cooling water. Accordingly, condensers are classified as air-cooled, water-cooled, or evaporative types.

In refrigeration systems with heat recovery and in heat pumps, the heat rejected in the condenser can also be used to heat water for industrial use or to generate space or process heat. A special design is the cascade cooler (see Section 1.1), in which the refrigerant in the low-temperature loop of a cascade compressor refrigerating system is liquefied by evaporating refrigerant in the high-temperature loop.

Air-Cooled Condensers. Air-cooled condensers (Fig. 19) are used in low- to medium-capacity refrigeration systems and, rarely, in large plants. This type of condenser is gaining

steadily in importance as freshwater becomes more scarce and more costly.

Figure 19. Air-cooled condenser
a) Refrigerant vapor inlet; b) Refrigerant condensate outlet

In very low-capacity equipment, such as home refrigerators, heat is rejected to the ambient air by free convection. In all other cases, cooling air is conveyed through the condenser, usually by several fans (forced-circulation condenser). Axial-flow fans are used when the condenser is installed outdoors; radial-flow fans are employed when additional resistance in air ducts must be overcome.

An air-cooled condenser consists of a system of tubes or hoses with fins on the air side to facilitate heat transfer. In this way, the external surface area is increased by a factor of 15 – 30. Steel tubes and fins used with ammonia as a refrigerant are galvanized to prevent corrosion and to provide a good heat-conducting surface. With halocarbon refrigerants, copper tubes and aluminum fins are generally employed. To improve heat transfer, the aluminum fins often have wavy edges and surface corrugation. The central tubes are commonly staggered in the direction of air flow to enhance turbulence. Fin spacing is 1.5 – 5 mm but should be at least 3 mm if dirty air is encountered. Heat-transfer coefficients referred to the total external surface are between 30 and 60 $\mathrm{W\,m^{-2}\,K^{-1}}$ for air face velocities of 2 – 4 m/s. The external surface area A required for heat rejection is determined by the relation

$$A = \frac{\dot{Q}_\mathrm{c}}{U \Delta t_\mathrm{m}}$$

where Δt_m is the logarithmic mean temperature difference between the condensing temperature t_c on the one hand, and the air inlet and outlet temperature on the other hand.

Air-cooled condensers are usually designed for a 10 – 15 K difference between the condensing temperature and the inlet air temperature. For economic reasons, small temperature differences are chosen for refrigeration systems with a high annual utilization, and larger differences are used when utilization is lower (e.g., in air conditioners).

If the condensing pressure becomes too low in the cold season, maintaining the needed flow of refrigerant through the expansion valve may not be possible. This is especially true of air-cooled condensers installed outdoors. To prevent this pressure loss, control of the condensing pressure is usually necessary. Control can be implemented by reducing the volume flow rate of air (blower speed control or shutoff of individual fans), altering the effective heat-transfer area (e.g., by impounding liquid refrigerant), raising the inlet air temperature by mixing it with recirculated hot air, or a combination of these methods.

A receiver is usually connected downstream of the air-cooled condenser. It prevents vapor from entering into the liquid line and, at the same time, compensates for dislocations of refrigerant caused by varying conditions in the system.

A venting device in the receiver removes foreign gases that have contaminated the refrigerant loop. (For water-cooled condensers, the vent can also be placed on the condenser.) The mixture of gas and refrigerant vapor in the top of the tank is cooled by evaporating refrigerant in the vent, so that the refrigerant condenses and flows back into the receiver. The foreign gases can then be released through a discharge valve without significant loss of refrigerant. A venting system is needed, in particular, when the evaporating pressure is < 0.1 MPa.

Water-Cooled Condensers. The most commonly used design is the horizontal shell-and-tube condenser (Fig. 20), which is used in systems with very small to very large capacities. Cooling water flows through the tubes in several

passes and the refrigerant condenses on the shell side. The end covers, containing the bends, are removable so that the tubes can be cleaned easily from the water side.

Figure 20. Water-cooled shell-and-tube condenser
a) Refrigerant vapor inlet; b) Refrigerant condensate outlet; c) Cooling water inlet; d) Cooling water outlet; e) Vent pipe

Table 4. Typical fouling resistances R_i for various cooling waters

Cooling water	Fouling resistance, $\times 10^{-4}$ m^2 K/W	
	$\leq$0.9 m/s *	>0.9 m/s *
Seawater	1	1
Brackish water	4	2
Water from cooling tower	2	2
Spring water	2	2
Stream water	4	2

* Water velocity

Sizing of this type of equipment is dictated not only by capacity, but also by the properties of the available cooling water.

Typical inlet water temperatures are

Spring water	10 – 15 °C
Stream water	15 – 25 °C
Seawater	20 – 32 °C
Water from cooling tower	25 – 35 °C

The water is commonly warmed 4 – 15 K (larger temperature differences for lower inlet water temperatures). The condensing temperature is generally 3 – 6 K above the outlet water temperature.

The relationship used to determine the heat-transfer area is the same as that for air-cooled condensers, but no allowance is made for superheating or subcooling temperatures.

The overall heat-transfer coefficient U depends on the coolant velocity w, the refrigerant, and the degree to which the inside walls of the tubes are contaminated. For shell-and-tube condensers in ammonia service, these effects can be seen in Figure 21. Typical fouling resistances R_i for various types of cooling water are given in Table 4.

Figure 21. Heat-transfer coefficients for shell-and-tube ammonia condensers
R_i = internal fouling resistance

Figure 22. Vertical condenser
a) Refrigerant vapor inlet; b) Refrigerant condensate outlet; c) Cooling-water inlet; d) Cooling-water outlet; e) Spiral inserts to guide water to tube wall

Although bare steel tubes are used for ammonia, tubes finned on the refrigerant side (area ratio $A_a/A_i = 4 - 6$) are usually employed

with halocarbon refrigerants because of poorer heat transfer. The tubes are made of copper or brass; with seawater, they are made of copper – nickel alloys. The heat-transfer coefficients for halocarbon refrigerants, referred to the external tube area, are $600 - 1200\,\mathrm{W\,m^{-2}\,K^{-1}}$ at $w = 1.5 - 3$ m/s when the fouling resistance $R_i = 1 - 2 \times 10^{-4}\,\mathrm{m^2\,K/W}$.

If the water is very dirty or space is limited, vertical condensers are used (Fig. 22). These shell-and-tube devices are open on the water side and easy to clean; under certain conditions, cleaning does not require shutdown. Cooling water enters from a distribution tank at the top and is led down the inside of the tubes by spiral vanes. Thus, the water falls as a film, while the refrigerant condenses on the outside of the tubes.

Figure 23. Cooling tower
a) Cooling-water inlet; b) Cooling-water outlet; c) Freshwater inlet; d) Spray nozzles; e) Cooling surface (fill); f) Water separator; g) Fan

For smaller capacities up to ca. 50 kW, double-pipe (coaxial) condensers are frequently used. An outer pipe, wound in a spiral encloses one or more central tubes, which carry water inside and are finned on the refrigerant side. This design is inexpensive, but difficulty in cleaning makes it unsuitable for use with dirty cooling water.

Because of the scarcity of spring water, water-cooled condensers are usually operated in conjunction with cooling towers; this allows water savings of ca. 95 % compared to freshwater operation. In the cooling tower (Fig. 23), warm cooling water is brought in contact with ambient air countercurrently. Because the partial pressure of water vapor in the air is lower than that of the cooling water, a small portion of the water evaporates and thus cools itself. The cooled water is collected in a catch basin and is then available to absorb heat again in the condenser.

Evaporative Condensers. An evaporative condenser combines the actions of a cooling tower and a water-cooled condenser. It is used for medium to large capacities when a cooling tower is not available and when cooling water is in short supply. Freshwater consumption is the same as that with a tower and water cooling.

The refrigerant condenses in a system of tubes (Fig. 24), which are sprayed with water from a tank. Air flows upward through the tube array either by free convection or, more often, by forced draft. The air absorbs the heat of condensation by evaporating water from the tube surfaces. The water level in the tank is held constant by freshwater supplied under float control. The mist collector above the array of pipes prevents water droplets entrained in the airstream from escaping.

Figure 24. Evaporative condenser
a) Refrigerant vapor inlet; b) Refrigerant condensate outlet; c) Freshwater inlet; d) Water circulation pump; e) Spray apparatus; f) Water separator; g) Blower

Figure 25 illustrates the relationships of surface loading, condensing temperature, and inlet-air enthalpy for an ammonia condenser. To prevent severe scaling on the tubes, inlet water must have a low hardness. Many designs feature finned desuperheater tubes, which are not sprayed with water on the air outlet side, as well as special tubes for subcooling the refrigerant.

1.1.4. Evaporators [3], [7], [15–17], [23], [27], [30], [33], [78–90]

Evaporators for Liquid Cooling. For moderate to very high refrigerating capacities, flooded *horizontal shell-and-tube evaporators* are used (Fig. 26). These devices consist of a cylindrical shell with tube sheets at either end; the tubes are fastened in the sheets by welding, soldering, or rolling. Bare or finned tubes, usually of steel, copper, or brass, are used as appropriate for the refrigerant and the surface loading. The liquid to be cooled is pumped through the tubes and can be redirected one or more times at the ends of the evaporator. The refrigerant evaporates from the outside of the tubes. Heat-transfer coefficients are 400 – 1200 W m^{-2} K^{-1}, depending on the secondary (brine) and primary refrigerants.

Entrainment of liquid refrigerant from the evaporator, which can occur especially at higher surface loading, is prevented by an impingement separator located in the tube-free part of the evaporator or by a separator (usually using the effect of gravity) placed above the evaporator.

Special devices must be provided to recycle the oil carried into the apparatus with the refrigerant. The type of device is dictated by the refrigerant and the service conditions. Ammonia is insoluble in oil, and by virtue of its higher relative density, oil collects at the bottom of the evaporator, where it can be withdrawn. With oil-soluble halocarbon refrigerants, a side stream of refrigerant – oil mixture must be withdrawn from the evaporator. The refrigerant must then be removed from the side stream by steam or electrical heating, or by heat exchange with warm refrigerant at the condensing pressure.

Figure 27. Shell-and-tube direct-expansion evaporator
a) Refrigerant inlet; b) Refrigerant vapor outlet; c) Brine inlet; d) Brine outlet

Because of the significant cost of recycling the oil, a different shell-and-tube evaporator design is often used with halocarbon refrigerants. In the *direct-expansion evaporator* (Fig. 27), refrigerant is completely evaporated in the tubes, while the liquid to be cooled is circulated around them by means of baffles. For water chillers especially, internally finned tubes are used instead of bare ones to enhance heat transfer on the evaporating side. If the tubes are connected in series so as to make several passes, improved heat transfer results from the increased mass flow density. However, the simultaneous pressure drop on the refrigerant side must be considered; this leads to a corresponding decline in the saturation temperature between the inlet and the outlet, and thus to a decrease in the mean temperature difference between the brine and the refrigerant. The heat-transfer coefficients re-

ferred to the external tube surface area may be 400 – 2000 W m^{-2} K^{-1}, depending on the brine being cooled and the tube design.

A *vertical-type evaporator* (Fig. 28) consists of a system of vertical, inclined, or hairpin tubes connected to one header at the top and another at the bottom, with a liquid separator in line downstream. The refrigerant stays at a constant level in the tubes as it evaporates, thus cooling the secondary refrigerant which is circulated around the tubes by an agitator. This kind of apparatus was formerly employed to cool brine in open vessels; today, it is used mainly as an ice-bank evaporator, where the ice frozen around the tubes is melted off periodically by the circulating water.

Figure 28. Vertical-type evaporator for ammonia
a) Refrigerant inlet; b) Refrigerant vapor outlet; c) Oil drain; d) Refrigerant separator; e) Agitator

Figure 29. Finned air cooler as direct-expansion evaporator
a) Refrigerant inlet; b) Refrigerant vapor outlet; c) Thermostat-controlled expansion valve; d) Sensor

A *parallel-plate evaporator* consists of several plates, connected in parallel, in which the refrigerant evaporates. The corrugated plates are welded or soldered together to form narrow channels, which may be horizontal or vertical. This kind of device can thus be employed in direct expansion or flooded mode. The plates are made of galvanized or lacquered steel or, in special cases, stainless steel. These units are employed as drinking-water and brine chillers and for ice storage. The heat-transfer coefficients are similar to those for vertical-tube evaporators under the same conditions.

Evaporators for Gas Cooling. Gases, especially air for space cooling, are cooled on the outer surface of *finned evaporators* (Fig. 29).

The apparatus consists of a system of tubes with bonded fins that are connected in series and parallel on the refrigerant side. The gas is usually drawn or forced through the system of fins by a blower connected to the evaporator; natural convection cooling is employed less often. When the gas is cooled, water or other constituents often condense or freeze. If a frost coating forms on the tubes and fins, continuous operation is possible only if the system includes a second unit. Defrosting is accomplished from the pressure side of the compressor with warm compressed gas, which gives up its heat of condensation to the cold surfaces of the apparatus; otherwise, electric heating rods can be built into the evaporator system. To eliminate frequent defrosting, fin spacings of 8 – 20 mm are used in air coolers with a frost deposit. In air conditioners for operation above the freezing point of water, compact systems with close fin spacings (ca. 2 mm) are used.

System capacities, materials, and tube or fin sizes vary widely. As with air-cooled condensers, galvanized steel is used in ammonia systems, and copper tubes with aluminum fins are used for halocarbon refrigerants.

With halocarbon refrigerants, as in the case of liquid chillers, direct expansion is used. The refrigerant is expanded into the tubes as a liquid – vapor mixture; it is completely evaporated and superheated by several degrees. Where a network of evaporators with finned units exists (e.g., in ammonia refrigerant plants), expanded liquid refrigerant is transported through the system by pumps. Part of the refrigerant evaporates, and the resulting vapor – liquid mixture goes to a collecting tank that also serves as a refrigerant separator.

Instead of the evaporating refrigerant, a secondary refrigerant can be pumped through the chiller. At air temperature $<0\,°C$, heat-transfer coefficients are relatively low (ca. 7 – 17 W m^{-2} K^{-1}) because of frost formation. At temperatures $>0\,°C$, values of up to 30 W m^{-2} K^{-1} can be achieved with some designs. At gas pressure significantly greater than 0.1 MPa, shell-

and-tube devices are used; like similar liquid chillers, these can be designed for flooded or direct expansion operation.

1.1.5. Other Equipment [6], [15], [18], [23], [30], [91–96]

Safe and economical operation of vaporcompressor refrigerating systems involves not only the main components (compressor, condenser, and evaporator) but also a number of additional components.

In *expansion devices,* refrigerant coming from the condenser is allowed to expand to the evaporating pressure. These devices must supply the evaporator with as much refrigerant as it needs under the prevailing service conditions. Expansion valve design depends mainly on the selected evaporator design. The manual control valves formerly in use have now been replaced by automatic valves. High-pressure float controllers relieve the pressure on the liquid coming from the condenser. They are used in plants employing flooded evaporators, as well as in pumped-circulation systems where the refrigerant is expanded in a vessel at the evaporating pressure and the liquid refrigerant is pumped to the evaporator. In flooded operation with a highly variable cooling load, a low-pressure float controller is preferred to keep the liquid level in the evaporator constant.

Constant-pressure expansion valves and thermostatic expansion valves are employed with direct expansion evaporators. *Constant-pressure expansion valves* control the liquid flow to the evaporator in such a way that the evaporating pressure remains constant. Control is satisfactory only at constant load, and therefore this approach is now seldom used.

Constant refrigerant level in the evaporator and thus good heat transfer are achieved with the *thermostatic expansion valve* (Fig. 30). A temperature sensor (c) downstream of the evaporator controls the expansion valve so that the refrigerant leaves the evaporator at a temperature a few degrees higher (usually 5 – 7 K) than the evaporating temperature. In conventional thermostatic expansion valves, a vapor pressure that is dependent on the sensor temperature acts on the control diaphragm to alter the opening of the valve. More recent designs of thermostatic expansion valves use electronic actuation, which offers better dynamic properties; this can be an advantage especially when the cooling loads vary rapidly.

Figure 30. Thermostatic expansion valve
a) Refrigerant inlet; b) Refrigerant outlet, c) Temperature sensor; d) Control diaphragm; e) Valve cone; f) Adjusting spindle

Along with the expansion valves used as primary controllers in the refrigerant loop, *secondary controllers* can also be employed. These devices include:

1) thermostatic postinjection valves,
2) constant-pressure valves, and
3) capacity controllers.

Thermostatic postinjection valves are used when highly superheated suction-side refrigerants lead to excessive compression temperatures. To prevent this, the valves inject liquid refrigerant from the condenser into the suction line. This process is usually controlled by a temperature sensor on the compressor discharge side. Constant-pressure valves are employed when a refrigerant loop contains several evaporators at different temperatures and the evaporating temperature must not go below a certain limit in one of the units (e.g., to prevent icing in a water chiller). Capacity controllers match the compressor capacity to the refrigerating effect. If the available compressor controls are not adequate, the capacity controller can bypass part of the compressed refrigerant to the compressor suction, thus preventing a drop in suction pressure.

Thermostats are used to maintain constant temperature in cooled rooms or in the liquid outlet from evaporators. If the sensor in the con-

trol unit detects a change in temperature, a compressor capacity stage is turned on or off. If the evaporating pressure is to be held constant, a low-pressure *pressostat* is used instead of a thermostat. The high-pressure pressostat carries out a corresponding function on the condenser side. Oil-pressure differential cutouts are employed as oil delivery monitors in compressors with pressurized oil lubrication.

For freshwater-cooled refrigerating systems, *automatic water valves* reduce water consumption. They control the flow rate of cooling water so that a constant condensing pressure is maintained, independent of the condensing capacity required.

Automatic shutoff, especially of refrigerant piping, is accomplished with *solenoid valves*. These devices enable, for example, the supply of refrigerant to an evaporator to be discontinued. If intermediate positions between open and closed are needed, as is often the case in cooling-water and brine loops, *motor-actuated valves* are used.

Pressure safety relief devices are employed to prevent excessive pressure in system components. These devices include rupture disks, pressure safety relief valves, and safety pressure cutouts. Their design and use must comply with applicable national safety provisions and standards (DIN 8975 in the Federal Republic of Germany).

Systems using halocarbon refrigerants often have *heat exchangers* to subcool the liquid refrigerant flowing to the control device and superheat the refrigerant vapor flowing to the compressor. The exchangers improve the coefficient of performance and volumetric refrigerating effect with many refrigerants (R 12), (R 502) and the filling ratio in direct-expansion evaporators; they also protect the compressor against intake of liquid refrigerant. As a rule, refrigerant vapor is led through internally finned tubes, while liquid moves through the baffled shell-side space of the apparatus in crosscurrent – countercurrent flow.

Filters in the refrigerant line keep the compressor and control valve free of solid contaminants. Halocarbon refrigerant loops include *dryers,* which prevent refrigerant degradation and icing in expansion valves on expansion below 0 °C. Refrigerating units must have *pumps* to transport cooling water, brine, or other secondary refrigerant, as well as primary refrigerant. Virtually all the pumps used are centrifugal. Whereas open pumps are commonly employed for secondary refrigerants, hermetically sealed (canned-motor) pumps are usually found in primary-refrigerant service. Because of the low static pressure differences to be overcome in finned air chillers or air-cooled and evaporative condensers, the *fans* used with these units are generally axial-flow types. Some air-conditioning evaporators and evaporative condensers also have radial-flow fans. To avoid cold losses, all components that operate under evaporating pressure and are located in ambient-temperature areas are provided with *insulation*. Insulating materials include cork, cellular glass, foamed polystyrene, and polyurethane. The most economical insulation thickness depends strongly on refrigerant and ambient temperatures; it should always be sufficient to prevent sweating. *Vapor locks* must be included to prevent the diffusion of water vapor.

1.2. Absorption Refrigerating Systems

[3], [8], [14], [27], [30], [97–106]

Absorption refrigeration systems differ from compressor refrigerating systems in two main respects: (1) The refrigerant vapor drawn out of the evaporator is compressed not by a mechanical compressor but by a thermal one, which consists of an absorber, a solution pump, and a generator. (2) Operation of the thermal compressor requires a solvent (a second working fluid) as well as a refrigerant. The most important refrigerant – solvent pairs are:

1) *ammonia – water*, used for evaporating temperatures between +10 and −60 °C, and
2) *water – lithium bromide solution*, used for evaporating temperatures >0 °C (air-conditioning systems).

Although many other pairs have been suggested and studied, none is widely used.

1.2.1. Ammonia – Water Absorption Refrigerating Systems

Figure 31 is a schematic diagram of a single-stage ammonia – water absorption refrigerating system.

Figure 31. Single-stage absorption refrigerating system
a) Generator with distillation section and reflux condenser; b) Condenser; c) Heat exchanger; d) Evaporator; e) Absorber; f) Solution pump; g) Solution heat exchanger; h) Expansion valve for weak solution; i) Expansion valve for ammonia; j) Solution pump drive motor

In the generator (a), ammonia is driven out of an ammonia-water solution by heating under high pressure. The refrigerant is distilled in a column, usually located inside the generator, and condensed (b). The condensate is subcooled (c) by cold vapor from the evaporator, then expanded to the evaporating pressure and fed to the evaporator (d), where it absorbs heat and evaporates. From there, the refrigerant vapor passes through the heat exchanger (c) to the absorber (e). The weak (ammonia-poor) solution in (e) absorbs the refrigerant vapor, and the resulting heat is rejected to cooling water. The solution, now more concentrated, is pumped through the solution heat exchanger (g) to the generator. In the solution heat exchanger, the enriched cold solution from the absorber is brought into thermal contact with the warm weak solution, which flows from the generator to the absorber through an expansion valve.

A thermodynamic description of the process in an absorption system involves the relationship of pressure p, temperature T, and concentration ξ. Figure 32 shows curves of vapor pressure vs. temperature at varying concentrations ξ. The curves are straight lines in the coordinates chosen. The operating points of the most important devices can be plotted on such a diagram. Condensation and evaporation are each represented by a single point, because they proceed at a constant concentration $\xi \approx 1$, whereas generation and absorption take place in the concentration range bounded by the rich and weak solutions (ξ_r and ξ_w).

Figure 32. Diagram of absorption refrigerating process ∗ (log p vs. $1/T$)
t_0 = Evaporating temperature; t_c = Condensing temperature; t_H = Generator final temperature
∗ See the text for definitions of ξ_r, ξ_w, $\dot{Q}_0$, $\dot{Q}_c$, $\dot{Q}_H$, $\dot{Q}_A$, and $\dot{Q}_R$.

The $h-\xi$ diagram devised for ammonia – water by MERKEL and BOŠNJAKOVIĆ is useful for thermotechnical determinations, because in this plot quantities of heat appear as lengths.

The process is specified in terms of three temperatures:

1) the generator final temperature t_H, which is determined by the heating medium;
2) the condensing temperature t_c, which is determined by the cooling water; and
3) the evaporating temperature t_0, which is dictated by the application.

The remaining quantities p_c, p_0, ξ_r, and ξ_w are thus defined.

The heat balance of the absorption refrigeration process is as follows:

$$\dot{Q}_H + \dot{Q}_0 + P_P = \dot{Q}_c + \dot{Q}_A + \dot{Q}_R$$

where $\dot{Q}_H$ is the rate of heat supply to the generator; $\dot{Q}_0$ is the refrigerating effect supplied to

the evaporator; P_P is the drive power of the solution pump; and $\dot{Q}_A$, $\dot{Q}_c$, and $\dot{Q}_R$ are the rates of heat removal in the absorber, condenser, and reflux condenser, respectively. In many cases, P_P can be neglected in comparison with the other quantities.

Instead of the coefficient of performance for the compression system, the heat ratio ($\dot{Q}_0/\dot{Q}_H$) is used here for thermodynamic assessment:

$$\zeta = \frac{\dot{Q}_0}{\dot{Q}_H + P_P} \approx \frac{\dot{Q}_0}{\dot{Q}_H}$$

This ratio indicates how much refrigerating effect can be accomplished by a given thermal power supplied to the generator at the evaporating temperature t_0. The heat ratio for today's large-capacity ammonia – water absorption systems is ca. 0.7 when $t_0 \approx 0\,°C$; between 0.47 and 0.40 for t_0 from -20 to $-30\,°C$; and between 0.34 and 0.25 for t_0 from -40 to $-50\,°C$.

In the case of compressor refrigerating systems, economic considerations dictate a shift to two-stage or multistage operation above a certain compression ratio that depends on the compressor design. By contrast, two-stage absorption systems are employed when the temperatures of the heating medium, the cooling water, and the evaporating temperature (which determine the concentration difference between the weak and rich solutions) take on values so unfavorable that this concentration difference becomes $<5\,\%$. In two-stage absorption systems, the two solvent loops are connected in series; the pressure difference between generator and evaporator is divided into two steps.

Changes in the process (e.g., the use of multistage absorption, the injection of cold rich solution into the distillation column, or multistage desorption) lead to further improvement in the heat ratio and to a reduction in the necessary temperature of the heating agent.

Absorption refrigeration systems can be driven by relatively low-grade heat, which is often available from industrial processes. The process can then be economically optimized for given heating media and cooling-water temperatures.

Alteration of the solution flow rate and the heating capacity allows infinitely variable control down to the lowest heat-removal rate. Up to ca. 10 % of the refrigerating capacity, a proportional decrease of the consumption rates of heating agent and cooling water can be expected.

The most important advantage of absorption refrigerating systems is that they can utilize waste heat. However, the following points are also important for the use of these systems: safety in operation, good part-load performance, adaptability to changing service conditions, and low noise emission. Investment costs and energy consumption are higher than for comparable compressor refrigerating systems, but the low price of waste heat can often be crucial in the decision to use an absorption system.

1.2.2. Equipment for Ammonia – Water Refrigerating Systems

Absorption refrigerating systems employing water – lithium bromide solution are used primarily in air-conditioning systems, because this combination of substances is nontoxic. These systems, usually factory-assembled, with capacities of 200 – 6000 kW, are distinguished by

compact design, noise- and vibration-free operation, and simple, continuous capacity control. Their drawbacks are relatively high energy consumption, heavy demand for cooling water, and cost of anticorrosion measures in various parts of the system.

Generator. The generator is most commonly heated by steam, off-gas, or liquids. Either horizontal or vertical flooded or sprayed tube systems (usually in a shell) are used. The generator is ordinarily combined into a unit with a distillation column and a reflux condenser (dephlegmator). In rare cases, the generator is fired directly with natural gas, oil, or kerosene (multipass combined flue and smoke-tube principle).

Figure 33 shows a schematic diagram of a vertical sprayed generator. The device consists of a solution vessel (d), a heating system (c), a distillation section (b), and a reflux condenser (a). The countercurrent motion of steam and solution creates good conditions for heat and mass transfer, and heat-transfer coefficients of ca. 2800 $W\,m^{-2}\,K^{-1}$ are achieved.

Rich solution coming from the solution heat exchanger enters the packed bed (m), where it absorbs part of the water from the ascending steam. The descending solution then encounters the upper tube sheet of the heating system (c); it passes through guide inserts to the inside of the tubes, where it is degassed. The weak solution is caught in a collector and fed back to the absorber. The expelled steam is rectified by rich warm solution in a packed bed, then by reflux from the condenser in the distillation section (b). Heat removal in the reflux condenser can be accomplished with cooling water or with cold rich solution.

Absorber. The absorber is usually a horizontal shell-and-tube device (see Fig. 34). Several such units can be placed one above another depending on the capacity requirement. A spray device (e) over the tube bundle (f) supplies weak solution to the outside of the tubes while cooling water flows through them. The refrigerant vapor to be absorbed enters the shell-side space from several points over the length of the apparatus.

Figure 34. Cross section of a shell-and-tube absorber employing the spray principle
a) Ammonia vapor inlet; b) Weak solution inlet ; c) Rich solution outlet; d) Vent connection; e) Spray device; f) Tube bundle

Another shell-and-tube design, which has the advantage of requiring little floor space, is the *vertical sprayed absorber* (tower absorber). The weak solution is supplied through a distributing system to the vertical tubes, while cooling water flows through the tubes. The refrigerant vapor flows upward countercurrently to the solution.

Heat-transfer coefficients for these absorber designs are between 400 and 800 $W\,m^{-2}\,K^{-1}$, depending on the operating conditions.

Figure 35. Solution heat exchanger
a) Rich solution inlet; b) Rich solution outlet; c) Weak solution outlet; d) Weak solution inlet

Solution Heat Exchanger. Weak solution is brought into thermal contact with rich solution in the countercurrent solution heat exchanger. Double-pipe heat exchangers are used for low transfer rates, and shell-and-tube devices for higher rates. The weak solution is usually inside the tubes, whereas the rich solution is transported through the shell-side space by a pump.

Figure 35 shows a high-capacity solution heat exchanger, consisting of several shell-and-tube units mounted one above another.

1.2.3. Water – Lithium Bromide Absorption Refrigerating Systems

The condenser and evaporator designs used in absorption refrigeration systems are largely the same as those employed in compression systems (Sections 1.1.3 and 1.1.4). Therefore, only the generator, absorber, and solution heat exchanger are discussed in this section. Other equipment worth mentioning includes extra heat exchangers, refrigerant and solution receivers, capacity controls, ventilation devices, and expansion valves.

Figure 36 is a schematic diagram of a lithium bromide absorption refrigerating system. The principal components are two vessels mounted one above the other. The lower vessel (a) contains the evaporator (c) and the absorber (d). The generator (e) and the condenser (f) are located inside the upper vessel (b). Because the system operates under a high vacuum, virtually no heat-transfer losses occur between the components in each vessel, despite the large temperature differences. A pump (g) delivers rich solution through the heat exchanger (h) to the generator, where part of the water is driven out of it.

Figure 36. Water – lithium bromide absorption system
a) Lower vessel; b) Upper vessel; c) Evaporator; d) Absorber; e) Generator; f) Condenser; g) Pump; h) Heat exchanger; i) Pump

The weak, high-temperature solution is recycled through the solution heat exchanger to the absorber, where the vapor from the evaporator is absorbed by cooling water. Steam produced in the generator is condensed in the condenser; the condensate flows to the evaporator, where it absorbs heat from the secondary refrigerant. Another pump (i) circulates refrigerant to spray the evaporator tubes; the refrigerant vapor produced is absorbed by the weak solution in the bottom part of the vessel. An inhibitor (usually lithium nitrate or lithium chromate) is added to the loop to combat corrosion.

Lower capacity water – lithium bromide absorption systems have attracted interest in connection with solar energy utilization.

1.3. Steam-Jet Systems [3], [5], [30], [107], [108]

The steam-jet refrigeration system can be regarded as a thermally driven compression system in which vapor is compressed in a jet apparatus. Its operation is illustrated in Figure 37.

Figure 37. Steam-jet refrigeration system
a) Nozzle; b) Diffuser; c) Mixing chamber; d) Condenser; e) Evaporator; f) Pump; g) Steam boiler; h) Expansion valve; i) Pump drive motor

Steam is generated at pressure p_1 in boiler (g); the mass flow rate of steam is $\dot{m}_1$. In the nozzle (a), the steam is expanded to the pressure p_0 prevailing in the evaporator (e); then, in the

mixing chamber (c), it is mixed with steam (rate $\dot{m}_0$, pressure p_0) from the evaporator. Next, the pressure of the two streams $\dot{m}_1$ and $\dot{m}_0$ is raised to the condensation pressure in the diffuser (b). Virtually all the kinetic energy is transformed to pressure. When heat is withdrawn in the condenser (d), the steam condenses. The condensate is divided into two substreams $\dot{m}_1$ and $\dot{m}_0$; $\dot{m}_1$ is delivered to the steam boiler (g) by a pump (f), and $\dot{m}_0$ is led to the evaporator through an expansion valve (h). Here, substream $\dot{m}_0$ evaporates at pressure p_0, absorbing heat; the exiting expanded steam, moving at a higher velocity, sucks this stream into the mixing chamber.

Water, employed mainly as working steam and as refrigerant in the steam-jet system, is a low-cost, hazard-free working fluid with a high specific enthalpy of evaporation. The pressure p_0 is usually between 0.6 and 1.2 kPa; p_c depends on the cooling-water temperature and lies between 3 and 8 kPa.

This system's drawbacks are the large specific volume in the region of the evaporating temperatures, the high vacuum, and the limitation placed on the evaporating temperature by the freezing point. Lower temperatures can be reached if hydrocarbons and halocarbon refrigerants are used as working fluids.

As in absorption systems, the decisive quantity for assessing this process in energy terms is the *heat ratio* ζ, which indicates how much refrigerating effect $\dot{Q}_0$ is gained from the heating power $\dot{Q}_H$ and the pump power P_p supplied (see Section 1.2.1). The heat ratios attained in practice are much lower than those for an absorption system. With multistage jet units and multistage evaporation, the energy performance can be improved.

The advantages of the steam-jet system are low plant costs due to the simple design, utilization of waste heat, small space requirement, and low maintenance costs. These are partly offset by the drawback of high operating costs, especially because of the large consumption of cooling water. These features make the steam-jet process suitable for short-term refrigeration using cheap waste heat.

1.4. Thermoelectric Refrigeration [3], [28], [109–112]

Thermoelectric refrigeration is based on the *Peltier effect*, which is the reversal of the Seebeck principle. In an electrical circuit consisting of two different conductors and a d.c. voltage source, one of the junctions between the two conductors is heated while the other is cooled. If the direction of the current is changed, the warm and cold junctions change places. Energy is lost by Joule heating in the conductors, because of their resistance, and by conduction from the warm junction to the cold one; these losses greatly reduce the coefficient of performance. The maximum temperature difference that can be produced between the junctions and the coefficient of performance are primarily determined by the properties of the two conducting materials: thermoelectric force e, electrical conductivity σ, and thermal conductivity λ. These are grouped into a parameter called the *figure of merit* z:

$$z = \frac{e^2 \cdot \sigma}{\lambda}$$

The thermoelectric force and the electrical conductivity should be as high as possible, while the thermal conductivity should be as small as possible. This requirement is best met by alloys of semiconducting materials, such as lead – tellurium, antimony – bismuth, and germanium – silicon (→ Semiconductors).

Because the capacity of a single Peltier element is very low, a number of elements must be connected in a thermally parallel manner so that their refrigerating effects are additive. Figures of merit z of $(3.0-3.5)\times 10^{-3}\,\mathrm{K}^{-1}$ can be attained with current semiconductor technology, so the available coefficients of performance are comparable with those of other processes only at very small refrigerating capacities.

Thermoelectric refrigeration is used in special cooling devices for laboratory purposes and in low-capacity air-conditioning units.

2. Industrial Applications of Refrigeration [10–13], [21], [31]

Many industrial chemical processes require low temperature, often in conjunction with large re-

frigerating capacity. Examples of design of refrigerating plants for these applications are described in this chapter. Machines and equipment for ice making, food technology, climate control, and construction are also discussed.

2.1. Chilling of Liquids [18], [24], [26], [28], [30], [33], [113–117]

Liquid chilling usually refers to the cooling of secondary refrigerants in order to transfer cold to other products. The use of secondary refrigerants is suitable when cold is to be distributed to several consumer locations or when contact between primary refrigerant and product resulting from leaks must be avoided. The selection of a secondary refrigerant depends on temperature, heat-transfer properties, material compatibility, toxicity, and price. Figure 38 shows the temperature ranges for the most important secondary refrigerants; the shaded part of each range should be avoided whenever possible, because of poor heat-transfer properties. The favorable qualities of water mean that it is almost always preferred when the evaporating temperature of the refrigerant is > 0 °C. Down to -40 °C, calcium chloride brines are commonly used with steel; ethylene glycol – water mixtures are used more and more because of their good behavior with respect to ferrous and nonferrous metals.

The concentrations of aqueous mixtures are chosen so that the freezing point lies several degrees below the evaporating temperature. Tables 5 and 6 list important data for calcium chloride brines and ethylene glycol – water mixtures.

Table 6. Important data for ethylene glycol – water mixtures

Density at 15 °C, kg/m^3	Glycol content, kg glycol/100 kg solution	Start of freezing, °C	Specific heat at 0 °C, kJ kg^{-1} K^{-1}
1005	4.6	− 2	4.10
1010	8.4	− 4	4.06
1015	12.2	− 5	3.98
1020	16.0	− 7	3.89
1025	19.8	−10	3.85
1030	23.6	−13	3.77
1035	27.4	−15	3.73
1040	31.2	−17	3.64
1045	35.0	−21	3.56
1050	38.8	−26	3.52
1055	42.6	−29	3.43
1060	46.4	−33	3.35

Equipment. With few exceptions, chilling of the secondary refrigerant or other liquid takes place in shell-and-tube heat exchangers. Direct-expansion-type evaporators are employed with halocarbon refrigerants at capacities of up to ca. 1000 kW. At higher capacities and with ammonia as refrigerant, flooded shell-and-tube evaporators are used.

Liquid-chilling machines for temperatures > 0 °C, with treated water as secondary refrigerant, are widely used, especially for air condi-

Figure 38. Application ranges of secondary refrigerants
Hatching indicates region of high viscosity

tioning, but also for manufacturing processes, food technology, cooling plastics machinery, etc. Nearly all of these units operate with halocarbon refrigerants.

Plants with reciprocating compressors are in service at refrigerating capacities up to ca. 1000 kW; above this range, centrifugal compressors are used most widely. Compact systems of this type are made for capacities up to ca. 5000 kW. These water chillers have compressor, evaporator, condenser, control, safety devices, and electrical switching; they are factory-assembled on a single frame, so that setup and commissioning are simple. Water- or air-cooled condensers are employed; in large air-cooled plants, the air-cooled condensers may be very large and, so separate placement of the water-chilling unit and the condenser (erected outdoors) is common. Virtually all water chillers with reciprocating compressors use R 22 as refrigerant.

Hermetic compressors are mainly employed at low refrigerating capacities up to ca. 50 kW, whereas semihermetic motor-driven compressors are used at higher capacities. Because air-conditioning service means frequent part-load operation, the refrigerating capacity is usually distributed between several smaller compressors, which can be turned on or off as needed. Larger units are also made with two separate refrigerant loops to enhance reliability.

Water chillers with screw compressors also use R 22 as their principal refrigerant. These units are distinguished by quiet operation and high reliability. Like reciprocating plants, they can be adapted to varying discharge pressures; this is important for air-cooled chillers. The compressors are driven by bipolar three-phase motors. In hermetic or semihermetic motor – compressors, the oil stream separation required on the discharge side of screw compressors can take place inside the motor space, so that compact construction is possible. In systems with a single compressor, capacity control is exerted with a slide valve; with several compressors, individual machines are turned on and off as in the case of reciprocating compressors.

Most centrifugal units use R 11 or R 12. The rotational speeds required are greater than bipolar three-phase motors can supply, so builtin gearing or frequency converters are employed. Even in large-capacity systems, semihermetic mounting of the drive motor and compressor is common. Both single-stage and two-stage units are built; the two-stage design with intermediate expansion offers somewhat better energy economy. Water chillers with centrifugal compressors usually feature water cooling, because of their high capacity and the inflexibility of centrifugal compressors with respect to varying discharge pressures. Whereas evaporators in systems with reciprocating and screw compressors operate in direct-expansion mode, centrifugal systems employ flooded evaporators. Usually a unit has just one compressor; part-load control is exerted by inlet guide vanes, the less economical bypass control being used only at cooling loads much lower than half the maximum capacity.

Units for chilling brine and other secondary refrigerant liquids are essentially similar in design to water chillers.

Very viscous or pasty liquids are chilled in screw or scraped-pipe coolers, whose walls are held at the required low temperature by evaporating primary refrigerant or by a secondary refrigerant. Such devices are frequently used in the food and chemical industries.

2.2. Separation of Liquids by Crystallization [13], [21], [118–123]

Recovering some products and separating materials from mixtures may require low process temperature, because of either the position of the thermodynamic equilibrium (solubility curves) or the temperature sensitivity of some substances.

For example, *p*-xylene is recovered from the mixture of ortho, meta, and para isomers by crystallization in a scraped-pipe heat exchanger (→ Xylenes); the process temperature is ca. − 70 °C. The xylene mixture flows inside a cylinder, while a stream of secondary refrigerant flows through the jacket. Scraper blades rotating inside the cylinder continuously remove the crystals precipitated on the wall and thus ensure constant heat-transfer conditions. Cold is produced in cascade-type refrigerating systems.

Figure 39 is a flow sheet of a cascade unit for chilling methane (secondary refrigerant) to − 77 °C. Both loops use three-stage centrifugal compressors; the high-temperature loop operates with R 12 and the low-temperature loop with R 13.

Another example is the dewaxing of crude oils. Alkanes left in the crude oil after distillation are crystallized by cooling to ca. −30 °C. The crystallizers, operating in several temperature stages, are similar in design to those used for xylene separation. The refrigerating systems are usually multistage ammonia compressor refrigerating systems or ammonia – water absorption refrigerating systems. Low-temperature fractional crystallization is also used to separate undesirable byproducts, especially when an impurity has a boiling point close to that of the desired product.

2.3. Cooling and Liquefaction of Gases [13], [21], [124–130]

Except in room air-conditioning systems (see Section 2.5), where air is used as secondary refrigerant, the purpose of cooling gases and gas mixtures is nearly always to bring about total or fractional condensation. The fractional condensation of gas mixtures effects separation; the desired product may be either the residual gas or the condensate.

A number of industrially important gases are produced by condensation from crude gases. The condensation temperature depends on the concentration of the gas in the mixture or on its partial pressure. The partial pressure can be raised by compressing the crude gas. The recovery (the ratio of gas condensed to gas in the feed stream) and the concentration of the gas in the feed are the chief factors dictating the temperature to which the crude gas must be cooled. Subsequent storage or transport of the condensed gas also determines the condensation temperature. Chlorine, ammonia, sulfur dioxide, and carbon dioxide are examples of important products recovered by condensation at subambient temperatures.

Chlorine is recovered between + 20 and − 50 °C, depending on the production process. Chlorine gas from electrolysis of sodium or potassium chloride contains, after preliminary treatment, 2 – 8 vol % air, hydrogen, carbon dioxide, and carbon monoxide (→ Chlorine, Chap. 11.). The choice for chlorine separation among the following three candidate processes depends on the chlorine content in the feed stream and the desired recovery:

1) The crude gas inlet at 0.1 MPa is condensed at this pressure. Multistage refrigerating systems may be needed (depending on the recovery) for evaporating temperatures at or below −45 °C.
2) The crude gas is compressed to ca. 0.3 MPa in nonlubricated reciprocating compressors (or centrifugal compressors when the quantity of gas is large). The increased partial pressure enables condensation to be carried out at evaporating temperatures of ca. − 15 to − 20 °C in the refrigerant loop.

Figure 39. Flow sheet of cascade centrifugal refrigerating system for xylene separation

– – – R 12 Loop; ⟶ R 13 loop

3) The crude gas is compressed to 1.0 – 1.5 MPa in several stages and can then be condensed with water; no refrigerating machine is needed.

⟶ Chlorine loop; - - - - Refrigerant loop

These processes are often linked. For example, part of the chlorine gas from the compressed crude gas can be condensed with water; the remaining gas is then cooled to ca. −40 °C and another fraction condenses. The recovery, depending on feed-gas composition, is >99 vol %.

Figure 40 is a flow sheet of a *chlorine liquefaction system.* The crude gas is first treated to remove water vapor and other gases, then led through a precooler (b). Here, evaporating chlorine cools the gas to ca. − 30 °C so that, on subsequent compression to ca. 0.4 MPa (c), the final temperature does not exceed 80 °C, the allowed maximum on safety grounds. The compressed gas is first cooled against water in a heat exchanger (d). It then goes to the first chlorine condenser (e), which is cooled by evaporating primary refrigerant. The condensed fraction flows to a receiving vessel (g). The uncondensed fraction continues to a second chlorine condenser (f), where it is collected at a lower temperature and led to the vessel.

Ammonia can be condensed from converter gas in low-temperature refrigerating systems (→ Ammonia). Evaporating temperatures of the two-stage refrigeration process are between −50 and − 60 °C.

In the separation of *sulfur dioxide*, the feed gas is first compressed to ca. 0.5 MPa; up to one half of the initial sulfur dioxide content is recovered by condensation at − 40 °C (→ Sulfur Dioxide). The gas is then expanded to ca. 0.1 MPa, the gas temperature drops to − 50 °C, and the remaining sulfur dioxide condenses.

Carbon dioxide for the beverage industry and for dry-ice production is purified by scrubbing and adsorption, then condensed at low temperatures and stored (→ Carbon Dioxide). Evaporating temperatures are ca. − 30 to − 35 °C.

For *tank storage and transport*, gases are liquefied and recondensed with cold-vapor refrigeration processes, provided their standard boiling points are not much lower than − 100 °C. This group includes ethane, ethylene, propane, propene, butane, butadiene, ammonia, and others. Gases such as ethane and ethylene, which have critical pressures near or below ambient temperature, are liquefied in the evaporator of a closed refrigerating system resembling a cascade system. The process takes place at elevated pressure between − 50 and − 30 °C. Figure 41 is a flow sheet of a plant that recondenses ethylene for storage at atmospheric pressure. Higher boiling substances are condensed either by compression and cooling against water or air, or in a closed refrigerating system at storage pressure. Recondensing units with gas compression represent a possible application for nonlubricated reciprocating compressors, because the product must not be contaminated with lubricating oil.

– – – R 22 loop; ⟶ Ethylene loop

In the *drying of gases*, particularly of compressed air, the dew point must be lowered to such an extent that no water vapor condenses during later use of the gas. Refrigerating system are often employed from 25 to 5 °C when water cooling is inadequate and adsorptive drying is ruled out for economic reasons. To minimize energy consumption, the dry cold gas can be used to precool the moist gas stream. Smaller units generally employ R 12 and R 22 and thermostatically controlled expansion; for high capacities, ammonia and flooded operation are preferred. Finned cooling systems are used at standard pressure, whereas shell-and-tube exchangers with smooth or shallow finned tubes come into play at higher pressures. If dew points $< +5$ °C are required, the water vapor collects as frost on the heat-exchange surfaces. It must be melted periodically by using electrical heating or pressurized refrigerant vapor. This arrangement calls for two evaporators connected in parallel and operated alternately. To avoid short cycle times, the greatest possible areas are provided on the gas side, so that the frost layer grows slowly. Finned coolers best meet this requirement; in shell-and-tube devices, the air is on the shell side to prevent the tubes from becoming plugged with ice.

In refrigeration systems, the use of condensation to recover valuable feedstock and solvent and to return them to the production process contributes to saving raw materials. To reduce water and air pollution, increasingly lower temperatures (down to − 70 °C) are employed for off-gas treatment and other purposes, in order to remove even slight traces of foreign and hazardous substances by recondensation.

2.4. Remote Cooling [61], [131], [132]

Like steam power plants, central cooling systems in large chemical plants generate needed energy and distribute it through a network of pipes that is often highly branched. Such installations are a special application of centrifugal compressor ammonia refrigerating systems. Even though the properties of ammonia are not favorable for centrifugal compressors (low molecular mass requiring many stages), the low price of ammonia and the small pipe cross sections and heat exchangers make ammonia the most economical refrigerant. The cold consumers, often several hundred meters away, are supplied directly with liquid primary refrigerant; no intermediate secondary refrigerant system is necessary.

Figure 42 is a flow sheet of a remote cooling system with two stages. Before expanding in evaporator (g), the warm liquid refrigerant is subcooled (e), by the vapor coming from the evaporator, and in this way the vapor is heated close to ambient temperature. Consequently, the vapor piping can be left uninsulated with no significant energy loss. Before the refrigerant vapor enters compressor (i), it is saturated with expanded liquid in order to minimize superheating on compression. Vapor coming from the low-stage compressor is intercooled against water in the surface cooler (j), and expansion takes place in several stages. In this way, such installations can be operated economically.

2.5. Air Conditioning [13], [21], [24], [25], [29], [31], [133–137]

In many industrial plants, air must be held in some definite state for the manufacture, processing, and storage of products. The necessary conditions are dictated by the need to keep the temperature, humidity, air velocity, and air purity within narrow ranges. Such requirements apply, for example, in the manufacture of textiles, tobacco products, and photographic or electronic equipment; in printing, food, or pharmaceutical plants; in special fabrication processes in the machinery industry; at data-processing facilities; and elsewhere.

Conditioned air consists of fresh and recycled air in some proportion; the cooling surfaces are always $> 0\,°C$. Two main processes are used to cool air in an air-contitioning plant:

1) Cooling and simultaneous humidification or dehumidification in a wet air cooler (air washer)
2) Cooling and simultaneous dehumidification in a surface cooler

When the outside air is polluted, it is purified by filtering, scrubbing, or adsorption before being mixed with recycled air. Water, cooled in the evaporator of a water chiller, is usually employed as secondary refrigerant (see Section 2.1). Many air-conditioning systems incorporate heat recovery to warm the air after dehumidification.

2.6. Refrigeration Plants for Cold Rooms and Freezers [10–12], [15–18], [21], [31], [138–158]

Refrigeration plants for cold rooms are used mainly for the preservation of foodstuffs of plant or animal origin → Foods, 2. Food Technology, Chap. 3.; they can, however, be used to extend the shelf lives of other products, such as chemicals, pharmaceuticals, or flowers. The principal users are cold-storage plants, slaughterhouses, breweries and dairies, refrigerator trucks and railroad cars, and stockrooms in food stores.

Aside from a few special cases, such as the humid air cooling of vegetables or flowers, refrigeration plants for cold rooms use direct cooling by evaporating refrigerant, with no intermediate circulation of a secondary refrigerant.

Storage requirements vary, from 10 to 0 °C for coolers and from − 20 to − 30 °C for freezers; accordingly, refrigerating equipment operates at evaporating temperatures from 0 to − 10 °C (single-stage compression) or from − 30 to − 40 °C (two-stage compression). Two basic types of systems exist:

1) A *centralized unit*, consisting of a large refrigerating system from which the condensed primary refrigerant is distributed to evaporators in the individual chambers

2) *A decentralized system*, in which each chamber has its own refrigerating unit that may have one or several compressors

In large cold-storage plants, slaughterhouses, and breweries, the usual refrigerant is ammonia. In mobile refrigerating systems and in food stores, R 22 or R 502 is preferred. Plants using ammonia are centralized; the liquid refrigerant flows by gravity or is pumped from a receiving and separating tank on the low-pressure side to the individual chamber coolers. The air coolers must be defrosted from time to time; this is usually done by passing hot gas through the refrigerant piping (Fig. 43).

Refrigeration plants for cold rooms operating on R 22 or R 502 can be centralized or decentralized. The air cooler in such a unit is generally a thermostatically controlled direct-expansion evaporator. Decentralized machines are simpler in design, but require a much greater number of refrigerant compressors than centralized systems and also consume more energy in most cases. Whereas hot-gas defrosting is common in centralized plants, electrical defrosting is often used in decentralized systems with direct-expansion evaporators.

The products to be stored may be cooled or frozen in the chambers themselves, but special equipment is usually employed for this purpose. Such equipment lowers the product temperature much more rapidly (see following discussion of " Freezing Processes").

The coolers in a chamber are mounted either along the walls or below the ceiling. Air is often distributed by a system of ducts below the ceiling, whereas it is commonly exhausted from the chamber without any special ductwork. The rate of air circulation depends on the size of the room and the products stored there; an air speed in the chamber of ca. of 0.5 m/s is often selected. Maintenance of a given humidity level in the air, usually between 85 and 95 % R.H., is very important. If the humidity is too high, product shelf life is shortened; if it is too low, the product will dry out. Adequate sizing of the air-cooler surfaces keeps the humidity from dropping too low. The accuracy of temperature and humidity control can be improved by using additional heating and humidifying equipment. Other measures can extend the shelf life of foodstuffs. In fruit storage, for example, the oxygen content of the air is generally lowered (storage under controlled atmosphere).

In cold-storage plants, flat construction is favored because of better transport conditions, even though it involves greater cold consumption and higher land costs. Cold room chamber loading, depending on product and room height, is between 2 and 4 t/m^2 of floor area. Proper insulation of cold-storage rooms is important; the thickness of insulation is matched to the chamber temperature. The insulation must also incorporate a vapor barrier. The costs of insulating a cold-storage plant are often of the same order as those for the entire refrigerating system.

Freezing Processes. *Freezing in liquid brine* (immersion freezing) is appropriate only for foods in liquid-tight packages, such as canned frozen juices and shrink-wrapped poultry. Heat transfer is equally good everywhere on the surface, especially for products with uneven surfaces, so that freezing times are short. The product, such as packaged poultry, is moved by conveyors through a tank containing the brine, a mixture of propylene glycol and water. After leaving the tank, the product must be rinsed with water to remove residual brine.

In *contact freezing*, small unit packages of uniform thickness are frozen in plate-type equipment. The plates are sometimes vertical but most often horizontal. A unit has up to 20 aluminum plates with integrally cast channels for refrigerant or brine. The packages are laid on sheets between the plates, and the plates are pressed against the fixed lowermost plate to produce good contact between the cooled plates and the product. After freezing is completed, the plates must be warmed briefly with a defrosting circuit so that they can be separated.

Liquid, pulpy, or pasty material can be frozen at high rates in a *scraped-surface freezer.* The product is fed onto a slowly rotating horizontal cylindrical surface cooled by primary refrigerant. The devices used for application and removal depend on the product. The form of the frozen product (powdered or flaked) depends on the scraping apparatus and the starting material. The process is continuous and can be adapted to prevailing requirements by varying the roller speed, the evaporating temperature, and the coating thickness.

∗ The upper switchover valves are closed and the lower ones opened for cooling; the opposite is true for defrosting.

Cold-Blast Freezing. Freezing in air is suitable for products of any type, size, or form, whether in the loose or packaged state; all frozen products are processed in this way. Many unit designs and ratings are available. Achieving economical freezing rates with air requires greater temperature differences than with contact or immersion freezing. Air temperatures of −30 to − 50 °C are used.

The product is conveyed through the freezing tunnel on wheeled racks, belts, carousels, or slide ways. In this continuous process, the material enters the freezing unit through locks. Multiple fans blow cold air countercurrently or crosscurrently over the product at up to 7 m/s. The air is cooled against refrigerant evaporating at roughly −40 to − 55 °C in finned-pipe heat exchangers. Freezing rates of ca. 1 – 3 cm/h can be attained. The residence or freezing time can be controlled continuously by varying the belt or chain speed or the feed rate.

The refrigerating equipment, usually two-stage, employs ammonia or R 22 as refrigerant. Reciprocating and screw compressors are used.

A special form of cold-blast freezing is the *fluidized-bed process*; this is particularly suitable for free-flowing materials in the form of small lumps or fine grains, which are often encountered in food technology and the chemical industry.

Cold air, blown upward through a metal pan with a perforated bottom, suspends the product and flows around it. The good heat transfer (coefficients of 90 – 300 W m^{-2} K^{-1} for specific surfaces of 0.25 – 1 m^2/kg) results in short freezing times, so that equipment can be made compact and space requirements minimized. The air, which must be cooled to ca. −30 °C usually is generally blown by fans through several finned-tube evaporators. Pressure drops in the evaporators and the fluidized bed must be considered. The optimal bed depth is determined by the type of product being frozen and is controlled through air velocity and particle size. The evaporators are defrosted automatically at intervals, without interrupting the overall process; the refrigerant, usually R 22, is conveyed through the loop by pumping.

Freezing with Boiling Liquids. Two freezing processes involving boiling liquids have found limited application. One employs liquid nitrogen; in the other, boiling R 12 is placed in direct contact with the product.

Liquid nitrogen is sprayed onto the product in a tunnel (Fig. 44). The product is precooled by the cold gas produced by evaporation. Fans (h) circulate the gas around the product to prevent surface cracking, which would otherwise occur if the uncooled product suddenly came in contact with liquid nitrogen (d), which boils at ca. − 190 °C. To avoid excessive residence times and thus overlong tunnels, the large temperature difference between the surface and the interior of the product is not equalized in the tunnel. The product only remains in the tunnel as long as is necessary to remove the heat needed to bring its average temperature down to its desired storage temperature. Final temperature equalization between the core and the surface occurs later dur-

ing frozen storage. With 1 kg of liquid nitrogen (1.245 L), some 330 kJ of heat can be removed from the product. The large temperature difference and good heat transfer allow quick freezing and thus good product quality. Liquid carbon dioxide can be used instead of liquid nitrogen.

With R 12, the liquefied refrigerant is brought into contact with the product, again in a tunnel. The refrigerant evaporates at a temperature of ca. −30 °C. In contrast to nitrogen, R 12 can easily be recondensed with a condenser mounted in the tunnel. The condenser is held at about −45 °C by a two-stage R 22 refrigerating unit. Withdrawing a given amount of heat requires much less energy than with liquid nitrogen, because of the higher evaporating temperature. For economical operation, refrigerant losses resulting from leaks in the tunnel and entrainment with product must not exceed 1 – 2 wt % of product.

Freeze Drying (see also → Drying of Solid Materials, Chap. 2.5.). Frozen-dried products are of better quality than conventionally dried products because of reduced cell damage.

Freeze drying consists of the following steps: (1) freezing and cooling of the product to ca. −20 °C, (2) evacuation to 50 – 100 Pa, (3) addition of heat of sublimation through heated plates, and (4) condensation of water vapor on cold surfaces (−40 to −60 °C). The residual water content is <2 %. Finely divided products are more suitable than coarse ones, because both the freezing time and, more important, the drying time are shorter. The main difficulty is to remove water vapor quickly from the interior of the product without causing local overheating of the exterior. To prevent oxidation during storage, freeze-dried products are packaged under vacuum or in a nitrogen atmosphere.

Cold is produced with multistage compression and absorption machines. The energy consumption is high (10 to 15 times that required for frozen-food production) because the required refrigerating capacity is about eightfold and the evaporating temperatures are 10 – 20 K lower. However, energy costs for three months' storage of frozen food are roughly the same as for freeze drying. Nevertheless, the process is much more expensive than frozen storage, so freeze drying of foods is not very important; it is used increasingly for high-quality food and pharmaceutical products.

Ice Making. Ice, especially in finely divided form such as "tube" or "snow" ice, is used for cooling products during transport (factory ships, refrigerator railroad cars, etc.). It also helps avoid drying. In the chemical industry, finely divided ice is used to absorb the heat of reaction. Ice plays an important part in concrete construction work, where it removes the heat of setting.

Figure 44. Quick-freezing apparatus with liquid nitrogen
a) Freezing tunnel with belt conveyor; b) Product feed; c) Product removal; d) Liquid nitrogen feed from supply tank; e) Control valve; f) Temperature sensor; g) Spray nozzle; h) Circulating fans; i) Suction blower

A further application is in cold storage. Large amounts of ice are often stored in nuclear reactor buildings, so that radioactive steam can be completely condensed on the stored ice if the steam pipes rupture. The storage of cold also allows better use of refrigerating capacity when cold demand is variable. Ice is frozen on a refrigerant evaporator (coiled-pipe or plate evaporator) located in an open, water-filled vessel. The water, which is close to 0 °C, serves mainly as a secondary refrigerant in food production, especially in dairies. When the demand for cold rises, the ice layer frozen on the evaporator coils is melted, providing additional cooling capacity. Ice-storage units are used in air conditioning, where ice produced with cheap nighttime power is used to meet peak daytime loads. In this way, refrigerating systems can be made smaller, power-connected load can be reduced, and energy costs can be lowered.

Figure 45. Schematic of a tube ice maker
a) Shell-and-tube heat exchanger; b) Freezing tubes; c) Upper water tank; d) Tube-side space of exchanger; e) Lower water tank; f) Water pump; g) Ice breaker; h) Ice chute; i) Draining screen; j) Belt conveyor

Tube Ice. Ice in short tubular pieces (diameter ca. 40 mm, wall thickness 8 mm) is produced in tube ice makers. Figure 45 shows such a machine. In a vertical shell-and-tube device, refrigerant evaporates in the shell-side space, while water from a tank flows through distributors and down the inside of the tubes. Some of the water freezes; the rest goes to a receiver, where a float controller admits fresh water to make up for the amount frozen. About twice an hour, a timer cuts off the water flow and admits pressurized gas from the condenser to start the defrosting process. The ice released from the tubes is broken, then passes over a draining screen and through a chute to a belt conveyor, which carries it to an ice hopper or directly to the consumer. For a tube ice maker operating with ammonia (evaporating temperature ca. − 12 °C) and having a capacity of ca. 400 kg/h, the specific cold consumption is ca. 780 kJ/kg of ice.

Flaked Ice. Ice in the form of thin flakes is made continuously in machines where freezing takes place on the inside or outside surface of a cylinder. Water is sprayed onto the inner surface of the cylinder from a revolving distributor; the cylinder is cooled from the outside by refrigerant evaporating in a jacket. The ice is removed by a revolving scraper. In another design, the cylinder is cooled from the inside by brine or evaporating refrigerant and rotates; the water feed and scraping devices are stationary. Capacities for this type of icemaking equipment are between 5 and 30 t/d.

Block Ice. Ice blocks are generally 1 m long and weigh 12.5 or 25 kg each. Water is charged into a large number of conical ice cells situated in an open brine tank. Because the brine used as secondary refrigerant is corrosive, the ice cells are made of lead-coated sheet steel or stainless steel. An agitator moves the brine to a vertical-tube evaporator in the brine tank, where it is chilled and then circulated around the ice cells. At a brine temperature of ca. − 7 °C, the freezing time is ca. 8 h for a 12.5-kg block or 19 h for a 25-kg block. After freezing, the ice cells are hoisted out of the brine tank and briefly dipped in warm water to release the ice blocks, which are then easily displaced by tipping.

To shorten the freezing time, double-walled ice cells are used in the "Rapid-Eis" freezing process. The refrigerant is evaporated in the jacket space and freezing is accelerated by means of an evaporator tube located inside the ice cell. To melt the ice and free it from the cell, the jacket and evaporator tube are connected to the condenser side of the refrigerating system. Drawbacks of this process are the high manufacturing costs and high mass of the ice cells, which must be designed for the refrigerant pres-

sure. The process can also operate with brine; cell costs are then lower. Refrigerating systems for this process are single-stage ammonia machines with reciprocating compressors.

Dry Ice. The method most commonly employed for producing dry ice (solid carbon dioxide) consists of expanding pressurized liquid carbon dioxide to ambient pressure; the temperature falls below the triple point and snowlike carbon dioxide is obtained (→ Carbon Dioxide, Chap. 9.). Roughly a third of the liquid is transformed to the solid state; the remaining gas is recycled. The carbon dioxide "snow" is molded into 12 – 100-kg blocks in hydraulic presses.

Dry ice sublimes at − 78.9 °C and has a heat of sublimation of 573 kJ/kg. It is used chiefly in the transport of deep-frozen products and, to a minor extent, in laboratory chilling apparatus.

2.7. Use of Cold in Construction [13], [21], [31], [159–162]

The heat of setting in concrete gravity dams ranges from 250 to 500 kJ/kg, depending on the aggregate used and the cement : sand ratio. This heat must be removed, especially in thick dams, so that it does not buildup and cause cracking. In *postcooling,* chilled water is pumped through pipes inside the structure; compact water-chilling plants are used for this purpose. About 75 000 kJ of cold is required per cubic meter of concrete. In *precooling*, excessive temperatures are prevented either by cooling the aggregate and water before mixing or by adding finely divided (flaked or tube-frozen) ice during mixing. Aggregate cooling is usually performed with chilled water, but other methods employing air chilled to − 20 °C also offer some operational advantages.

When tunneling or similar construction work requires shaft sinking in water-bearing ground, the ground around the planned excavation is stabilized by freezing. Double-walled pipes are driven into the soil. A secondary refrigerant (usually brine) at − 20 to − 40 °C flows down the inner pipe and returns through the outer space. The time required for freezing with these parallel pipes depends on the type and size of the excavation, the spacing of the pipes, and the temperature of the secondary refrigerant; months are often necessary. Transportable brine-cooling units with reciprocating or screw compressors, using ammonia as primary refrigerant, are employed.

2.8. Air Refrigeration in Mining [13], [163–165]

The temperature and humidity in mines often become so high that ordinary ventilation with outside air is inadequate. Refrigeration equipment can be set up below ground in the shaft, or central cooling plants can be erected at the surface to produce cold water, which is then led to air coolers near the working face.

Refrigerating systems for underground installation are compact, transportable, explosion-proof units that cool air to ca. 18 – 20 °C and dehumidify it. The air is introduced into the ventilation tubing ca. 50 – 100 m before the road ending. The plants usually have watercooled condensers and employ R 22 or R 12 as refrigerant. Such machines can be driven by a compressed-air motor instead of an electric motor.

2.9. Artificially Cooled Skating Rinks [13], [21], [31], [166]

An artificially cooled skating rink consists of tubes embedded in a concrete slab that rests on a frost-proof base. The pipes are parallel, spaced some distance apart, and ca. 25 – 30 mm below the surface. A secondary refrigerant (usually brine), evaporating ammonia, or R 22 is pumped through the pipes. The surface temperature of the ice over the entire rink surface must stay within narrow limits; stringent requirements thus apply to both the supply of secondary or primary refrigerant and the control system.

3. Heat Pumps [167–172]

Heat pumps operate on the refrigeration principles described in Sections 1.1 and 1.2. The process is shifted toward higher temperatures, and the temperature of the rejected heat allows a medium to be heated for a given application.

The economic significance of the heat pump lies in the saving of primary energy in thermotechnical processes. The useful energy consists partly of primary energy and partly of energy from the surroundings or another heat source.

In a heat pump driven by an *electric motor,* the heat rejected in the condenser is used for heating. The process is assessed from the energy standpoint in terms of the coefficient of performance ε, which is the ratio of thermal power to power consumption:

$$\varepsilon = \frac{\dot{Q}_c}{P_{el}}$$

It is determined essentially by the temperatures in the heat-source loop and the useful-heat loop.

An electrically driven heat pump is evaluated economically over a given span of time in terms of the average coefficient of performance β, which is the ratio of the heat generated to the electrical work consumed during this period:

$$\beta = \frac{Q_c}{W_{el}}$$

In many applications, the compressor is driven by an *internal-combustion (gas or diesel) engine.* Heat from the engine coolant and from the engine exhaust is used in addition to that produced in the condenser.

The heating medium absorbs heat in the condenser, and is then delivered by a pump to the motor coolant heat exchanger and, subsequently, to the exhaust heat exchanger. In this way, useful heat is obtained at higher temperatures than in heat pumps with electrical drive.

With regard to primary energy utilization, this heat-pump system is very economical as a heating method because a substantial part of the primary energy applied is available for heating purposes, and heat from the surroundings or some other heat source is also used.

Heat pumps driven with primary energy (including absorption heat pumps) are characterized by the performance ratio ζ. This quantity is the ratio of thermal power to power supplied by the fuel:

$$\zeta = \frac{\dot{Q}}{P_F}$$

The average performance ratio γ is, accordingly, defined as

$$\gamma = \frac{Q}{W_F}$$

where Q is the useful heat generated in the interval under consideration and W_F is the fuel energy consumed in the same interval.

The components used in heat-pump systems are largely the same as those in compression and absorption refrigerating systems. In heat pumps with internal-combustion drives, the engines and their control and monitoring equipment are supplemented by heat exchangers for recovering heat from the coolant and exhaust. Most such exchangers are of the shell-and-tube type.

With R 114, the thermal stability of the halocarbon refrigerant limits the temperature of the useful heat to between 100 and 130 °C. In general, however, these temperatures are between 50 and 80 °C when R 12 is used as refrigerant.

The most important application of heat pumps in industry is the generation of process heat, especially for drying, in the food industry, and for process technology. Heat generation with heat pumps is especially economical when the coupled production of cold and heat is possible, as in galvanizing, plastics fabrication, or food technology.

n	number of plates in the upper section of the column
o	outside; ambient
r	refrigerant
rev	reversible
R	rejected
sat	saturation

1. Introduction

Cryogenic technology deals with the development and utilization of low-temperature processes and equipment. The field of cryogenics generally involves systems that operate at temperatures below −150 °C (123 K) [1]. This dividing line between the cryogenic temperature range and the field of ordinary refrigeration is selected because the normal boiling points of the so-called permanent gases, such as helium, hydrogen, nitrogen, and oxygen, lie below −150 °C, whereas the freon refrigerants, hydrogen sulfide, ammonia, and other conventional refrigerants all boil above −150 °C.

2. Uses

Applications of cryogenic technology vary widely, both in scope and size. Some of the areas involving cryogenic technology are discussed briefly in this chapter.

Rocket Propulsion Systems. Many of the large launch vehicles used in the United States space program use liquid oxygen as the oxidizing agent [2]. The first flight test of a liquid-fuel rocket using liquid oxygen was made by Robert H. Goddard in 1926. The NASA Saturn V Apollo vehicle used liquid oxygen as the oxidizing agent for all three stages and liquid hydrogen as the fuel for the upper two stages. The Space Shuttle propulsion system uses liquid hydrogen as the fuel and liquid oxygen as the oxidizing agent.

Cryogenic fluids are used because of the high specific impulse (thrust per unit mass flow rate) that can be achieved with the hydrogen – oxygen combination. The fluids must be in the liquid phase so that a sufficient mass may be stored on board within a reasonable volume.

The use of liquid hydrogen as a fuel in space vehicles introduces several special problems in addition to the problem of the low density of the fluid. Because the normal boiling point of liquid hydrogen is only 20.3 K, ambient air liquefies on the outside of an exposed, uninsulated liquid hydrogen storage tank. The condensed air on the tank poses safety problems and results in excessive heat transfer to the cold liquid hydrogen. To avoid this problem, liquid hydrogen tanks must be insulated.

Liquid hydrogen has the second lowest viscosity of all liquids (liquid helium has the lowest viscosity), which makes ordinary sealing difficult. In many cases, the only solution is to use a welded construction, which makes component disassembly and inspection both complicated and expensive.

An advantage of liquid hydrogen is that it can be used as the coolant for rocket nozzles. Liquid hydrogen is usually at a pressure of ca. 7 MPa before it is injected into the combustion chamber. Because the critical pressure of hydrogen is ca. 1.3 MPa, no problems of two-phase flow occur in the nozzle coolant passages with regenerative cooling.

Manufacturing Processes. Oxygen is required in the *steel-making process*, and the economical production of oxygen involves separation of the components of air in a cryogenic system [3]. In the open-hearth process, the conventional use of air as the gas above the molten charge in the furnace requires additional heating by an auxiliary fuel. The use of oxygen allows the operation of open-hearth steel furnaces at ≥130 % of the capacity when air is used.

High-strength pressure vessels may be constructed by cryogenic forming, in which the cylinder is stretch-formed at liquid nitrogen temperatures. This process (called Ardeforming) involves placing the fabricated vessel in a bath of liquid nitrogen (77.4 K) and introducing high-pressure gaseous nitrogen into the vessel. The vessel is allowed to expand by ca. 15 % into a stainless steel die of the appropriate shape. After

this stretching process, the vessel is allowed to warm slowly to room temperature. An improvement in tensile strength as high as a factor of 3 has been observed.

Tool steels used in manufacturing processes have been cryogenically treated to improve wear resistance of the tool [4]. The tool steel is cooled slowly (cooling rate ca. 3 °C/min) to liquid nitrogen temperatures and is then allowed to soak at the cryogenic temperature for ca. 20 h. During this process, essentially all of the retained austenite in the tool steel is transformed to martensite, which is a more wear resistant phase (→ Steel). The useful lifetime of parts, such as slitter knives, high-speed drills, etc., has been increased by a factor of 3 – 6 by this technique.

Recycling of Rubber. One of the more difficult materials to recycle is automobile or truck tire. Each year, $(160-200) \times 10^6$ tires are scrapped in the United States alone [5]. By a conservative estimate, these tires contain ca. 1.5×10^6 t of rubber that could be reclaimed and recycled. The conventional reclamation method involves chemical devulcanization of the rubber and mechanically grinding the resulting material. The widespread use of steel-belted tires makes this process uneconomical today.

When rubber is cooled to a temperature below 210 – 175 K, it passes through a glass transition and becomes brittle. In this brittle condition, the rubber can be crushed easily into small particles. The cord and metal components in the original tire can be separated readily by magnetic and air blast techniques.

The *freezing process* is usually carried out in a freezing tunnel, in which the rubber is carried along by a conveyor belt and liquid nitrogen is sprayed onto the surface of the scrap tires. The vapor that is formed when the liquid nitrogen evaporates is recirculated through the tunnel by a series of fans which increase the velocity of the nitrogen gas. The high velocity of the gas enhances the heat transfer process and improves the effectiveness of the freezing process. After passing through the freezing tunnel, the material is transferred immediately to a size-reduction mill, where the cord and metal components in the original tire are separated from the rubber particles in a single operation.

The crumb rubber particles are virtually free of fiber and steel contaminants. This property allows the rubber to be used in a variety of applications, including highway repairs using tire – asphalt mixes, soil conditioning, and mixing with coal for use as a fuel extender.

Currently, the cryogenic process is the only economically effective method to recover the rubber from steel-belted radial tires.

Food Processing and Transportation. Freezing as a technique for preserving food was used as early as 1840.

Currently, frozen foods are prepared by moving the food packages on a conveyor belt through a liquid nitrogen spray in a specially insulated tunnel. Initial contact with the liquid nitrogen freezes all exposed surfaces and seals in both the flavor and aroma of the food product. The food packages are then passed through an "equilibrium zone" in the tunnel that is cooled by the cold nitrogen vapor.

The cryogenic food freezing process has several advantages over the conventional food freezing process that uses cold air. Cryogenic freezing requires ca. 7 min compared with ca. 30 min required by conventional freezing methods. In conventional freezing, ca. 3 – 15 wt % (primarily water) of the product is removed by the air blast. In contrast, cryogenic freezing results in only 0.2 – 0.3 wt % dehydration [6]. This reduction in moisture loss results in improved flavor, texture, and appearance of the frozen food when compared with the resulting product of conventional freezing. The cryogenic freezing system is fairly simple and requires ca. 10 % of the maintenance expenditures of a conventional system.

Liquid nitrogen has also been used as the refrigerant in frozen-food transport trucks and railway cars [7]. The system consists of an insulated container for the liquid nitrogen and a series of nozzles that are activated by a thermostatically controlled switch to spray liquid nitrogen into the refrigerated compartment. The system is quite versatile in that the foods may be maintained at any prescribed temperature. Temperatures lower than those economically achieved by mechanical refrigeration may be maintained with the cryogenic system. Moisture retention of the cargo is good because the inert atmosphere inside the storage space prevents oxidation and drying.

Electronics. Sensitive microwave amplifiers (masers) are cooled to liquid nitrogen or liquid helium temperatures to assure that thermal vibrations of the atoms of the amplifier element do not seriously degrade the performance of the system. Cryogenically cooled masers are used in radio astronomy applications and in communication systems such as the Telstar satellite [3, pp. 157 – 170]. These systems use a compact, continuously operating, closed-cycle helium refrigerator to maintain a temperature as low as 4.2 K.

Tiny superconducting elements, called SQUIDs (superconducting quantum interference devices), are used in extremely sensitive digital magnetometers and voltmeters [8]. In addition to SQUIDs, other electronic devices that use superconductivity in their operation include superconducting amplifiers, transformers, and magnets. Superconducting magnets (solenoids) are used as levitation systems for trains that operate at speeds up to 500 km/h [9]. These trains are used for commuter service between Tokyo and Osaka in Japan. The levitation system consists of a normal track conductor coil on the ground and a superconducting coil on board the train. The superconducting coils are maintained at liquid helium temperature (4.2 K) by means of a cryostat filled with liquid helium. The propulsion unit for the train is a linear induction motor, with the primary coil located on the ground and the secondary coil placed on the train.

Biological and Medical Applications. Containers cooled by liquid nitrogen are used to preserve whole blood, tissue, bone marrow, and animal semen for extended periods of time [10]. Glycerol is mixed with such material as bull semen to protect the cells during freezing. The semen is slowly cooled to ca. 5 °C and is maintained at this temperature for at least 5 h to allow the glycerol to penetrate the cells adequately. The cells are then cooled at 1 °C/min to −15 °C and then at 5 °C/min to −79 °C. The frozen material can then be stored indefinitely at −196 °C in liquid nitrogen.

Whole blood cells have been preserved by placing the blood in a flat metal container and immersing the container in liquid nitrogen. The blood is thawed for use by abrupt immersion in an agitated bath of warm water. Whole blood has also been frozen by spraying it directly into liquid nitrogen. Cryogenic surgery (cryosurgery) has been used in eye surgery and for the treatment of Parkinson's disease and various lesions. This surgical technique has several advantages over conventional surgery, including reduced problems with bleeding, greater control of the area of influence, and less trauma to the system [11].

Several special-purpose probes have been developed for cryosurgery. Generally, liquid nitrogen (or sometimes liquid argon) flows through a vacuum-insulated cannula to the exposed tip on the probe and freezes the tissue to be destroyed. The size of the frozen region is controlled by adjusting the mass flow rate of cryogen through the cannula.

3. Liquefaction Systems

Several different systems are used to liquefy cryogenic fluids. To compare the thermodynamics of these systems, the thermodynamically ideal liquefaction system must first be established [12]. The perfect refrigeration cycle is the Carnot cycle. However, liquefaction is essentially an open-system arrangement. Therefore, the ideal liquefaction system only requires the first two processes in the Carnot cycle, which are a reversible isothermal compression followed by a reversible adiabatic (isentropic) expansion process to the saturated liquid. The ideal process is shown in Figure 1.

The gas to be liquefied is compressed reversibly and isothermally from ambient conditions (point 1) to some high pressure (point 2). This high pressure is selected such that the gas will reach the saturated liquid-state point (point f) on expansion through a reversible isentropic expander.

By applying the first law of thermodynamics to the system consisting of the compressor, expander, and liquid receiver, the following equation is obtained:

$$Q_{\mathrm{rev}} - W_{\mathrm{id}} = q_{\mathrm{m}} (h_{\mathrm{f}} - h_1)$$

where Q_{rev} = heat transfer from the ideal compressor, W_{id} = total ideal work requirement, q_{m} = mass flow rate through the system, h_{f} = specific enthalpy of the liquid, and h_1 = specific enthalpy of the gas at ambient conditions. The heat transfer process for the ideal

Figure 1. Thermodynamically ideal system for gas liquefaction ∗
A) Schematic: a) Isothermal compressor; b) Isentropic expander
B) Liquefaction thermodynamics
∗ Numbers on the temperature – entropy diagram correspond to similarly numbered points on the schematic diagram; f: fluid state

compressor is reversible and isothermal. Using the second law of thermodynamics gives

$$Q_{\mathrm{rev}} = q_{\mathrm{m}} T_1 (s_2 - s_1) = q_{\mathrm{m}} T_1 (s_{\mathrm{f}} - s_1)$$

where T_1 = ambient temperature, s_{f} = specific entropy of the liquid, s_1 = specific entropy of the gas at ambient conditions, and s_2 = specific entropy of the gas leaving the compressor ($s_2 = s_{\mathrm{f}}$). Substitution for the reversible heat transfer in the first expression gives the expression for the ideal work or the minimum work requirement for liquefaction of a gas:

$$-W_{\mathrm{id}}/q_{\mathrm{m}} = T_1 (s_1 - s_{\mathrm{f}}) - (h_1 - h_{\mathrm{f}}) \quad (1)$$

The negative sign appears in Equation (1) because of thermodynamic sign convention (i.e., work done by the system is positive; work done on the system is negative). The ideal work requirements for several common cryogenic fluids are given in Table 1.

3.1. Joule – Thomson Effect

Most liquefaction systems use an expansion valve or Joule – Thomson (J – T) valve to produce low temperature. Because heat transfer and kinetic energy changes are negligible and because there is no work transfer for the flow process through an expansion valve, the process is isenthalpic. The constant enthalpy lines on the temperature – pressure plane are shown in Figure 2. The effect of change in temperature for an isenthalpic change in pressure is represented by the *Joule – Thomson coefficient*, μ_{JT}, defined by

$$\mu_{\mathrm{JT}} = \left(\frac{\partial T}{\partial p}\right)_h$$

The Joule – Thomson (J – T) coefficient is the slope of the isenthalpic lines in Figure 2. In the region where $\mu_{\mathrm{JT}} < 0$, expansion through the valve (a decrease in pressure) results in an increase in temperature, whereas in the region where $\mu_{\mathrm{JT}} > 0$, expansion results in a decrease in temperature. The curve that separates the two regions is called the *inversion curve*. The J – T coefficient is zero along the inversion curve, because the slope of the isenthalpic line is zero.

Table 1. Ideal work requirements for liquefaction of gases beginning at 300 K and 101.3 kPa

Gas	Normal *bp*, K	Ideal work of liquefaction, kJ/kg
Helium [^{4}He]	4.21	6 819
Hydrogen	20.27	12 019
Neon	27.09	1 335
Nitrogen	77.36	768.1
Air	78.8	738.9
Carbon monoxide	81.6	768.6
Argon	87.3	478.6
Oxygen	90.2	635.6
Methane	111.7	1 091

Figure 2. Temperature – pressure diagram for a real gas

Thermodynamics shows that the J – T coefficient may be expressed in terms of other thermodynamic properties as follows [13]:

$$\mu_{\mathrm{JT}} = \frac{1}{c_p}\left[T\left(\frac{\partial v}{\partial T}\right)_p - v\right] \quad (2)$$

where v is the specific volume of the material. For an ideal gas, $v = (RT)/p$ and

$$\left(\frac{\partial v}{\partial T}\right)_p = \frac{R}{p} = \frac{v}{T}$$

where R = gas constant and p = pressure. Substitution into Equation (2) gives $\mu_{\mathrm{JT}} = 0$ for an ideal gas. For a real gas, the J – T coefficient may be either negative or positive, depending on the temperature and pressure. One equation of state for gases, which illustrates the behavior of real gases, is the *van der Waals equation of state:*

$$\left(p + \frac{a}{v^2}\right)(v - b) = RT$$

where the constant a gives a measure of the intermolecular forces between the gas molecules, and the constant b gives a measure of the finite size of the gas molecules. The expression for the J – T coefficient for a van der Waals gas is given by Equation (3):

$$\mu_{\mathrm{JT}} = \frac{(2a/RT)(1 - b/v)^2 - b}{c_p\left[1 - (2/vRT)(1 - b/v)^2\right]} \tag{3}$$

where c_p = specific heat at constant pressure. For large values of the specific volume, Equation (3) can be approximated by

$$\mu_{\mathrm{JT}} = \frac{1}{c_p}\left(\frac{2a}{RT} - b\right)$$

This expression shows that the J – T coefficient is positive when $T < 2a/bR$ and negative when $T > 2a/bR$. The inversion curve is represented by all points at which the J – T coefficient is zero. The inversion temperature from Equation (3) is given by

$$T_{\mathrm{i}} = \frac{2a}{bR}(1 - b/v)^2$$

The maximum inversion temperature for a van der Waals gas is the temperature on the inversion curve where $p = 0$ (or $b/v = 0$) or $T_{\mathrm{i,\,max}} = 2a/bR$. The maximum inversion temperature (in K) for several gases is as follows:

Helium [^{4}He]	45
Carbon monoxide	652
Hydrogen	205
Neon	250
Argon	794
Air	603
Oxygen	761
Nitrogen	621
Methane	939

The maximum inversion temperatures for helium, hydrogen, and neon are below ambient temperature. Therefore, liquefaction systems that use J – T expansion alone to produce low temperature cannot be used to liquefy these gases beginning at ambient temperature. Additional effects, such as precooling or expansion engines, must be used in liquefaction systems for these gases.

3.2. Basic Linde – Hampson System

Historically, the Linde – Hampson system was the second system used to liquefy gases at cryogenic temperatures (the cascade system was used first) [14]. The Linde – Hampson liquefaction system is shown in Figure 3 (see next page).

The gas is compressed (a) from ambient conditions to a pressure of ca. 20 MPa. The high-pressure gas then flows through a heat exchanger (b), in which the gas is cooled by heat exchange with the return stream of cold, low-pressure gas. At point 3, the cold high-pressure gas is expanded through a Joule – Thomson valve (c) to a pressure of the order of ambient pressure. At the exit of the valve (point 4), the stream is in the two-phase (liquid – vapor) region. The liquid phase is collected in the liquid receiver (d) and withdrawn. The saturated vapor is returned through the heat exchanger to furnish cooling for the incoming warm gas.

The liquid yield, or fraction of the warm gas stream that is liquefied, is given by

$$y = \frac{(q_{\mathrm{m}})_{\mathrm{f}}}{q_{\mathrm{m}}} = \frac{(h_1 - h_2) - (Q_{\mathrm{o}}/q_{\mathrm{m}})}{h_1 - h_{\mathrm{f}}}$$

where $(q_{\mathrm{m}})_{\mathrm{f}}$ = mass flow rate of liquid; q_{m} = total mass flow rate; Q_{o} = heat inleak from ambient; h_1 = enthalpy at the outlet at the warm end of the heat exchanger; h_2 = enthalpy at the inlet at the warm end of the heat exchanger; and h_{f} = enthalpy of the saturated liquid (fluid). (The numerical subscripts refer to the corresponding points in Figure 3.) The liquid yield may also be written in terms of the effectiveness of the heat exchanger, defined by

$$e = \frac{h_1 - h_{\mathrm{g}}}{h_1' - h_{\mathrm{g}}}$$

where h_1' = enthalpy of the low-pressure stream at pressure p_1 and at temperature $T_1{}' = T_2$;

h_g = enthalpy of the saturated vapor. If the heat exchanger were ideal, the cold gas would leave the warm end of the heat exchanger at the same temperature as that of the inlet temperature of the warm stream. The actual exit temperature of the cold stream is

$$T_1 = T_1' - (1-e)\left(T_1' - T_g\right)$$

Figure 3. Linde – Hampson liquefaction system ∗
A) Schematic: a) Compressor; b) Heat exchanger; c) J – T valve; d) Liquid receive
B) Liquefaction thermodynamics
∗ Numbers on the temperature – entropy diagram correspond to similarly numbered points on the schematic; f: fluid state; g: vapor state

The term $(1 - e)$ is called the heat exchanger ineffectiveness [15]. The liquid yield for the Linde – Hampson system may be written in the alternative form:

$$y = \frac{\left(h_1' - h_2\right) - (1-e)\left(h_1' - h_g\right) - \left(Q_o/q_m\right)}{\left(h_1' - h_f\right) - (1-e)\left(h_1' - h_g\right)} \quad (4)$$

The heat exchanger effectiveness must be close to unity for the system to produce liquid. The minimum heat exchanger effectiveness may be found from Equation (4) by setting the liquid yield equal to zero. The result is

$$e_{min} = \frac{\left(h_1' - h_2\right) - \left(Q_o/q_m\right)}{\left(h_1' - h_g\right)} \quad (5)$$

A typical value of e_{min} for a nitrogen liquefier operating between ambient pressure and temperature (101.3 kPa and 300 K) and 20.3 MPa is ca. 0.86. The power requirement for the compressor is given by Equation (6):

$$-\frac{W}{q_m} = \frac{T_2\left(s_1' - s_2\right) - \left(h_1' - h_2\right)}{\eta_c} \quad (6)$$

where η_c = isothermal efficiency of the compressor. The negative sign is included in Equation (5) because work is done on the gas by the compressor. An important performance parameter for liquefaction systems is the figure of merit (FOM), defined by

$$\mathrm{FOM} = \frac{\left(-W_{id}/q_m\right)}{\left[-W_{act}/\left(q_m\right)_f\right]} = \frac{y\left(-W_{id}/q_m\right)}{\left(-W_{act}/q_m\right)}$$

where W_{act} = actual work requirement. Performance values for the Linde – Hampson system using various gases are given in Table 2 (see next page).

The basic Linde – Hampson system cannot be used to liquefy gases such as helium, hydrogen, and neon, which have a maximum inversion temperature lower than ambient temperature. For these gases at ambient temperature, the enthalpy difference $(h_1' - h_2)$ is negative; therefore, the calculated value of the liquid yield from Equation (4) is negative. The system can never get started from the warm condition, because the gas would experience an increase in temperature when it expands through the J – T valve at ambient temperature. Even if the system could be cooled somewhat initially, the gas would expand through the J – T valve into the vapor region

Table 2. Performance of the Linde – Hampson liquefaction system for different fluids [a]

Fluid	Normal *bp*, K	Liquid yield $y = (q_m)_f/q_m$		Work per unit mass liquefied, kJ/kg		FOM[b]	
		Ideal[c]	Actual[d]	Ideal[c]	Actual[d]	Ideal[c]	Actual[d]
N_2	77.4	0.0708	0.0581	6673	11 620	0.1151	0.0661
Air	78.8	0.0808	0.0672	5621	9 653	0.1313	0.0765
CO	81.6	0.0871	0.00749	5381	8 934	0.1428	0.0860

CH_4	111.7	0.1977	0.1888	3957	5 919	0.2758	0.1844

[a] State points are $p_1 = 101.3$ kPa, $p_2 = 20.265$ MPa, $T_2 = 300$ K. [b] Figure of merit. [c] Ideal system operates with $e = 1.00$ and $\eta_c = 1.00$, heat transfer from ambient is neglected. [d] Actual system operates, $e = 0.975$ and $\eta_c = 0.7$, heat transfer from ambient is neglected.

and completely miss the two-phase region [12, pp. 71 – 73].

The designer of a liquefaction system has little freedom in choosing the conditions at point 1, which is usually near ambient temperature and pressure. However, the designer can select the maximum pressure (at point 2) in the Linde – Hampson liquefaction system. To maximize the liquid yield for the system, the optimum pressure at point 2 must be the pressure that minimizes the enthalpy h_2. Mathematically, for minimum h_2, the following must apply:

$$\left(\frac{\partial h}{\partial p}\right)_{T=T_1} = 0$$

From the chain rule of calculus,

$$\left(\frac{\partial h}{\partial p}\right)_T = -\left(\frac{\partial h}{\partial T}\right)_p \left(\frac{\partial T}{\partial p}\right)_h = -c_p \mu_{JT}$$

Therefore, the pressure that minimizes h_2 is the pressure for which $\mu_{JT} = 0$; i.e., point 2 should lie on the inversion curve. For air at 300 K, the corresponding pressure is ca. 400 MPa. However, practical systems are generally designed to minimize the work per unit mass liquefied. The optimum pressure to achieve this condition can be found by numerical methods. For air, the optimum pressure at point 2 to minimize the power input per unit mass liquefied is ca. 20 MPa [14, p. 71].

3.3. Precooled Linde – Hampson System

A plot of the liquid yield y as a function of the temperature at the inlet of the heat exchanger (point 2) for the basic Linde – Hampson system is shown in Figure 4 for liquefaction of nitrogen. The performance of the liquefier can be improved if it is modified such that the gas enters the heat exchanger at a temperature lower than ambient temperature. This is the basic principle of the precooled system shown in Figure 5.

Figure 4. Yield of liquid nitrogen ∗ [$y = (q_m)_f/q_m$] for the Linde – Hampson liquefaction system as a function of the temperature of the gas at the warm end of the heat exchanger (see Fig. 3)
∗ Yield is mass fraction compared to ideal system.

A separate refrigeration system, using a fluid such as ammonia or a freon compound, is used to precool the main gas stream. The critical temperature of the auxiliary coolant must be greater than ambient temperature so that the precoolant can be condensed by using a condenser cooled with water or ambient air.

Figure 5. Precooled Linde – Hampson liquefaction system
a) Main compressor; b) Heat exchanger; c) J – T valve; d) Liquid receiver; e) Refrigerant compressor; f) Refrigerant condenser

The temperature at point 3 is limited by the minimum temperature of the precoolant at point d. This factor also places an upper limit on the liquid yield for this system.

The liquid yield for the precooled Linde – Hampson system is given by Equation (7):

$$y = \frac{(h_1 - h_2) + r\,(h_a - h_c) - (Q_o/q_m)}{(h_1 - h_f)} \tag{7}$$

where $r = (q_m)_r/q_m$ = refrigerant mass flow rate ratio; h_a = enthalpy of the auxiliary refrigerant at point a; and h_c = enthalpy at point c. The second term in Equation (7) represents the improvement in liquid yield over the basic Linde – Hampson system because of the use of precooling. The power requirement per unit mass flow rate through the main compressor is given by Equation (8):

$$-W/q_m = \frac{T_1\,(s_1 - s_2) - (h_1 - h_2)}{\eta_c} + r\,(h_b - h_a) \tag{8}$$

The last term in Equation (8) represents the additional work required by the auxiliary refrigeration system. Another limiting factor in the design of the precooled system is that the refrigerant mass flow rate $(q_m)_r$ must be small enough so that the liquid entering the heat exchanger at point d can be completely vaporized. If the auxiliary refrigerant is not completely vaporized at point a, the liquid enters the refrigerant compressor and damage to the compressor results.

3.4. Linde Dual-Pressure System

The basic Linde – Hampson system may be modified, as shown in Figure 6, by compressing only a portion of the main gas stream through the entire pressure range [16].

Figure 6. Linde dual-pressure liquefaction system
a) Low-pressure compressor; b) High-pressure compressor; c) Heat exchanger; d) J – T valve; e) Liquid receiver

In the Linde dual-pressure system, the gas to be liquefied is compressed from near ambient pressure to an intermediate pressure (a)

and then to a high pressure (b) after a return stream has been added. The high-pressure gas is passed through a three-channel heat exchanger (c) and expanded to an intermediate pressure, where some of the gas is liquefied. The vapor is returned through the three-channel heat exchanger to the high-pressure compressor. The liquid stream is finally expanded to the low pressure of the cycle.

The liquid yield for the dual-pressure system is given by

$$y = \frac{(h_1 - h_3) - \left[(q_\mathrm{m})_\mathrm{i}/q_\mathrm{m}\right](h_1 - h_2)}{(h_1 - h_\mathrm{f})}$$

where $(q_\mathrm{m})_\mathrm{i}$= mass flow rate of the intermediate pressure stream at point 8, and q_m= mass flow rate through the high-pressure compressor. The work requirement per unit mass compressed in the high-pressure compressor is given by

$$-W/q_\mathrm{m} = [T_1(s_1 - s_3) - (h_1 - h_3)]/\eta_\mathrm{c} - \left[(q_\mathrm{m})_\mathrm{i}/q_\mathrm{m}\right][T_1(s_1 - s_2) - (h_1 - h_2)]/\eta_\mathrm{c}$$

The work per unit mass liquefied may be determined from the following:

$$-W/(q_\mathrm{m})_\mathrm{f} = (-W/q_\mathrm{m})/y$$

Figure 7. Work required to liquefy a unit mass of air in the Linde dual-pressure system ∗
∗ The intermediate pressure is the pressure of the gas between the low- and high-pressure compressors.
∗∗ Values for $(q_\mathrm{m})_\mathrm{i}/q_\mathrm{m}$

The work requirement for liquefaction of air in the Linde dual-pressure system is shown in Figure 7 (see below). At an optimum value of the intermediate pressure, the system work requirement is minimized for a given mass flow rate ratio, $(q_\mathrm{m})_\mathrm{i}/q_\mathrm{m}$. In addition, the work requirement for a given intermediate pressure is decreased by increasing the mass ratio. The mass ratio is thermodynamically limited, however, because $(q_\mathrm{m})_\mathrm{i} + (q_\mathrm{m})_\mathrm{f}$ must be less than the mass flow rate q_m through the high-pressure compressor.

3.5. Claude Liquefier

Expansion through a J – T valve is an irreversible process; therefore, the performance of a liquefaction system can be improved by removing energy by expansion through a turbine or expander [17]. The Claude system, shown in Figure 8, uses an expander (c) to provide the bulk of the cooling effect in the system.

The liquid yield for the Claude system is given by Equation (9)

$$y = \frac{(h_1 - h_2) + x\eta_\mathrm{ad}(h_3 - h'_\mathrm{e})}{(h_1 - h_\mathrm{f})} \tag{9}$$

Figure 8. Claude liquefaction system
a) Compressor; b) Heat exchanger; c) Expander; d) J – T valve; e) Liquid receiver

where $x = (q_m)_e/q_m$ = expander mass flow ratio; $(q_m)_e$ = mass flow rate through the expander; η_{ad} = adiabatic efficiency of the expander; and h'_e = enthalpy at the expander outlet for an isentropic expansion. If the expander work is used to aid the compression of the gas, the work requirement per unit mass compressed is given by Equation (10):

$$-W/q_m = [T_1(s_1 - s_2) - (h_1 - h_2)]/\eta_c - x\eta_e(h_3 - h'_e) \quad (10)$$

where η_e = overall efficiency of the expander. In addition to the improved thermodynamic performance of the Claude system compared with that of the basic Linde – Hampson system, the Claude system has the advantage that it may be used without precooling for liquefaction of helium, hydrogen, and neon. If precooling is used for these gases, however, the system performance is improved significantly.

3.6. Liquefaction Systems for Natural Gas

Several plants for production of liquefied natural gas (LNG) operate on a modified cascade system, called the *mixed refrigerant cascade* (MRC) system [18], as shown in Figure 9. Operation of the system is possible because natural gas is composed of several components that condense at different temperatures. These component liquids are used to cool the feed stream, without requiring separate cooling circuits for the fluids, by carefully controlling the composition of the refrigeration cycle gas.

The natural gas feed stream generally enters the MRC system at ca. 4 – 5 MPa. The refrigerant cycle gas is compressed (a_1) and partially condensed in the compressor aftercooler. The propane-rich liquid phase is separated from the mixture (c_1), expanded through a J – T valve, and used as the coolant in the warm three-channel heat exchanger (b_1). The vapor from the phase separator is passed through the three-channel heat exchanger and partially liquefied; the ethane-rich liquid phase is separated in a second separator (c_2) to provide cooling in the intermediate three-channel heat exchanger (b_2). The vapor (which is mainly methane) from the second-phase-separator is cooled in the intermediate three-channel heat exchanger, expanded through a J – T valve, and recirculated to provide cooling in the cold three-channel heat exchanger (b_3).

3.7. Collins Helium-Liquefaction System

One of the most important developments in cryogenic liquefaction systems since the original construction of the Linde – Hampson and Claude liquefiers occurred in 1946 [19]. During that year, a helium liquefier was developed by Samuel Collins of the Massachusetts Institute of Technology. Commercial application was initially handled by the A. D. Little Co. of Cambridge, Mass.; later, commercial development

was assumed by an associated company, Cryogenic Technology, of Waltham, Mass. The introduction of the Collins helium liquefier transformed the existing situation, where research at liquid helium temperature was restricted to a few laboratories that were willing to endure the difficulties of constructing and operating helium liquefiers of their own design. The maintenance and operation of the special-purpose liquefiers were both difficult and expensive, whereas the Collins system was relatively simple to operate and required minimum maintenance because of its robust design (Fig. 10).

Figure 10. Collins helium liquefaction system
a) Compressor; b) Heat exchanger; c) Expander; d) J – T valve; e) Liquid receiver

Helium is compressed (a) to a pressure of ca. 1.27 MPa, and any entrained oil is removed in an oil trap. The compressed helium gas flows through the first heat exchanger (b_1), and a fraction (ca. 16 %) is bypassed through the first expander (c_1). The helium gas enters the expander at a temperature of 40 – 45 K. The remainder of the helium gas stream flows through the second heat exchanger (b_2), and leaves the heat exchanger at a temperature of ca. 15 K. A fraction of the stream (ca. 56 % of the total inlet flow) is then bypassed to the second expander (c_2). The remainder of the helium stream flows through the third heat exchanger (b_3) and expands through a J – T valve (d), in which a fraction of the stream is liquefied. The vapor formed during the expansion process is returned through the heat exchangers to provide cooling for the incoming helium gas stream.

The unit is enclosed in a Dewar vessel with a liquid-nitrogen-cooled shield to reduce ambient heat transfer. The heat exchangers and expanders operate in an atmosphere of low-pressure helium gas, so that minor leaks from the engines do not cause significant problems.

The liquid yield for the two-expander Collins liquefaction system is given by

$$y = \frac{(h_1 - h_2) + x\Delta h_e + x'\Delta h'_e}{h - h_f}$$

where $x = (q_m)_e/q_m$ = mass flow rate ratio for engine 1, $x' = (q_m)'_e/q_m$ = mass flow rate ratio for engine 2, Δh_e = enthalpy change through engine 1, and $\Delta h'_e$ = enthalpy change through engine 2. The expander work output in the Collins system is generally not used to aid in compression, but the energy is dissipated in a mechanical or hydraulic brake, which is external to the system. Liquid nitrogen is generally used to precool the system and to improve liquid yield. Typical operating characteristics of the Collins system are as follows [20]:

Liquid He production	25 – 32 L/h
Power requirement (He only)	45 kW
Helium compressed	5.2 kg/h
Liquid nitrogen consumption	25 L/h
Power requirement (including power for liquid N_2) per unit volume	3.1 kW · h/L

Collins liquefiers have also been constructed with as many as five expanders, depending on the inlet pressure of the helium gas.

3.8. Miniature Liquefaction Systems

Miniature cryogenic liquefaction systems have been used in two special applications: (1) cooling of electronic components in aerospace systems (particularly cooling of infrared detectors) and (2) providing cooling for cryosurgery applications. In both cases, liquefaction is based on the Linde – Hampson cycle.

Hymatic Cooler. A miniature liquefier used to cool electronic components is shown in Figure 11 [21]. Because of the small cross-sectional

area of the heat exchanger tubing, the system requires extremely pure air or nitrogen in its operation.

Figure 11. Miniature liquefier (Hymatic system)
a) Filter; b) Finned-tube heat exchanger; c) Center mandril; d) Outer jacket; e) Porous nozzle; f) Cold space

A sintered bronze filter (a) of 2 µm pore size at the inlet of the system excludes particles in the incoming stream. The heat exchanger (b) consists of miniature finned tubing wrapped around a center mandril (c). The outer jacket (d) around the tubing coil confines the flow of the return gas stream around the tubing. The high-pressure gas (6 – 40 MPa) flows inside the heat exchanger tube and is cooled by the return cold gas flowing over the fins.

The high-pressure gas expands through a porous nozzle into the cold space chamber, where the liquid formed during the expansion process is used to cool the electronic components.

Freezing of contaminant gases, such as CO_2 and water vapor, presents a serious operational problem with this type of liquefier. Typical maximum allowable concentrations of contaminants are as follows:

H_2O	1 mg/kg (dew point −77 °C)
CO_2	1.2 mg/kg
Hydrocarbons	0.045 mg/kg

CVI Liquefier. A similar miniature liquefier unit, using gaseous argon as the working fluid was developed by the CVI Corp. (Fig. 12), [22].

Figure 12. CVI liquefaction system for cryosurgery applications
a) Argon cylinder; b) Filter and dryer; c) Control valve; d) Temperature indicator; e) Heat exchanger; f) Capillary tube; g) Vacuum jacket; h) Probe tip

Compressed argon from a standard gas cylinder (a) passes through a filter and drier unit (b) to remove impurities. The heat exchanger (e) in the CVI system consists of miniature, spirally finned tubing wrapped around a formed mandril. The mandril grooves and spacers wrapped between the tube and the outer casing force the return gas stream to flow axially along the outside of the tube, thereby improving the effectiveness of the heat exchanger. The heat exchanger is 16 mm in diameter and 76 mm in length. The J – T valve is replaced with a fine capillary tube (f) having an inside diameter of a few micrometers. The liquid produced during the expansion process is passed through the cryosurgery probe

tip (h), where cooling freezes the tissue on the outside of the probe tip.

Precise temperature control is achieved by automatic or manual control (c) of the gas flow rate into the unit. A thermocouple in the tip senses the temperature of the probe tip. A small resistance heater within the probe tip is used when rapid thawing is required, as in eye surgery or retraction of the probe from a frozen tumor. The liquefier is enclosed in a vacuum jacket (g) having a 25-mm outside diameter to reduce heat transfer to the internal parts of the probe and to allow the probe to be hand-held.

3.9. Comparison of Liquefaction Systems

The thermodynamic performance of the liquefaction systems described in Sections 3.2, 3.3, 3.4, 3.5, 3.6, 3.7, and 3.8, which use nitrogen as the working fluid, is given in Table 3 [23]. The first table entry is the thermodynamically ideal system, which has a liquid yield (y) of unity and a figure of merit (FOM) of unity. The remaining entries are presented for an ideal system (100 % effective heat exchangers and 100 % efficient compressors and expanders) and for a system with efficiency (η_c) and effectiveness (e) values commonly encountered in liquefier design.

The ideal precooled system and the ideal dual-pressure system have approximately the same FOM; however, the ideal Claude system has a significantly higher FOM. On the other hand, the Claude system is more sensitive to component inefficiencies. For example, the FOM of the basic Linde – Hampson system is decreased by a factor of 1.7 when component inefficiencies are included, whereas the FOM for the Claude system is decreased by a factor of 2.2 when inefficiencies are introduced. The performance of the Claude system is particularly sensitive to the efficiency of the expander, because a significant fraction of the cooling effect in the system is provided by expansion of the gas through the expander.

Table 3. Comparison of liquefaction systems ∗

Liquefaction system	Conditions	Liquid yield ∗∗ [$y=(q_m)_f/q_m$]	Work per unit mass liquefied ($-W/m_f$), kJ/kg	Figure of merit ∗∗ (FOM)
Ideal reversible system		1.000	768	1.000
Linde – Hampson				
Ideal system	$p_2=20.3$ MPa; $\eta_c=100$ %; $e=1.00$	0.071	6673	0.115
Practical system	$p_2=20.3$ MPa; $\eta_c=70$ %; $e=0.975$	0.058	11620	0.066
Precooled Linde – Hampson				
Ideal system	$r=0.15$; $p_2=20.3$ MPa; $T_3=240$ K; $\eta_c=100$ %; $e=1.00$	0.122	3945	0.195
Practical system	$r=0.15$; $p_2=20.3$ MPa; $T_3=240$ K; $n_c=70$ %; $e=0.975$	0.108	6317	0.122
Linde dual-pressure				
Ideal system	$p_2=6.1$ MPa; $p_3=20.3$ MPa; $\eta_c=100$ %; $(q_m)_i/(q_m)=0.80$; $e=1.00$	0.049	3679	0.209
Practical system	$p_2=6.1$ MPa; $p_3=20.3$ MPa; $\eta_c=70$ %; $(q_m)_i/(q_m)=0.80$; $e=0.975$	0.035	7346	0.105
Claude				
Ideal system	$p_2=6.1$ MPa; $x=0.60$; $\eta_c=\eta_{ad}=\eta_e=100$ %; $e=1.00$; $T_3=250$ K	0.258	1025	0.750
Practical system	$p_2=6.1$ MPa; $x=0.60$; $\eta_c=70$ %; $\eta_{ad}=80$ %; $\eta_e=72$ %; $e=0.975$; $T_3=250$ K	0.201	2232	0.344

∗ In all cases, the systems use nitrogen as the working fluid and are assumed to operate between 101.3 kPa at 300 K (26.8 °C) and the conditions stated; heat transfer from ambient is neglected.

∗∗ Compared to ideal reversible system; yield is the ratio of the mass of liquid produced to the mass compressed in the compressor.

4. Cryogenic Refrigeration Systems

Cryogenic refrigeration systems, called *cryocoolers*, are used in a variety of applications in which low temperature is required, including cooling of advanced electronic systems, superconducting magnets and motors, and space environment simulation chambers. In addition to cryocoolers that provide cooling by liquefying the working fluid, several others, including the Philips (based on the Stirling cycle), the Gifford–McMahon, and the Vuilleumier (VM), use entirely different concepts. Two special cryocoolers, i.e., the magnetic refrigerator and the dilution refrigerator, are used to achieve and maintain temperatures below 1 K.

4.1. Thermodynamically Ideal Refrigerator

The thermodynamically ideal refrigerator used for comparing the performance of real-life refrigerators is one of two types: (1) the *Carnot refrigerator*, for systems in which heat is absorbed by the refrigerator at constant temperature, and (2) the *isobaric-source refrigerator*, for systems in which the working fluid absorbs energy at constant pressure over a range of temperatures.

The figure of merit (FOM) for a refrigeration system is defined as the ratio of the ideal work requirement to the actual work requirement, for the same refrigeration effect. The FOM may be written in terms of the coefficient of performance (COP), defined by

$$\mathrm{COP} = \frac{Q_\mathrm{A}}{-W_\mathrm{net}} = \frac{Q_\mathrm{A}/q_\mathrm{m}}{-W_\mathrm{net}/q_\mathrm{m}}$$

where Q_A = energy absorbed from the low-temperature region, and W_net = net work input to the refrigerator; the work input is negative according to the thermodynamic sign convention. The FOM is then defined by Equation (11):

$$\mathrm{FOM} = \frac{(\mathrm{COP})_\mathrm{act}}{(\mathrm{COP})_\mathrm{id}} \tag{11}$$

where the subscripts act and id denote actual and ideal, respectively. The COP for the Carnot refrigerator depends only on the low and high temperatures of the cycle, and is given by Equation (12):

$$(\mathrm{COP})_\mathrm{id} = \frac{T_\mathrm{l}}{T_\mathrm{h} - T_\mathrm{l}} \tag{12}$$

where T_l = low temperature in the cycle, and T_h = high temperature in the cycle (usually ambient temperature). The COP for the isobaric-source ideal refrigerator is given by Equation (13):

$$(\mathrm{COP})_\mathrm{id} = \frac{h_2 - h_1}{T_\mathrm{h}\,(s_2 - s_1) - (h_2 - h_1)} \tag{13}$$

where points 1 and 2 are shown on Figure 13. If the specific heat of the material is approximately constant, Equation (13) may be written in terms of the temperatures, as follows:

$$(\mathrm{COP})_\mathrm{id} = \frac{T_2 - T_1}{T_\mathrm{h} \ln\,(T_2/T_1) - (T_2 - T_1)} \tag{14}$$

Equation (14) reduces to the expression for the Carnot COP (Equation 12) in the limit as T_2 approaches T_1.

Figure 13. Thermodynamic cycle for the reversible isobaric-source refrigeration system

4.2. Joule–Thomson Refrigerators

Any of the liquefaction systems that do not use an expansion engine may be classed as Joule–Thomson (J–T) cryocoolers when operated as a refrigerator instead of as a direct liquefier. A schematic of a typical J–T cryocooler is shown in Figure 14. The refrigeration effect, $Q_\mathrm{A}/q_\mathrm{m}$, for this system is given by

$$Q_\mathrm{A}/q_\mathrm{m} = \left(h_1' - h_2\right) - (1-e)\left(h_1' - h_\mathrm{g}\right)$$

where e = heat exchanger effectiveness, h_1' = fluid enthalpy at pressure p_1 and temperature T_2, and h_g = saturated vapor enthalpy. The

work requirement per unit mass for the compressor is given by Equation (6); therefore, the COP for the J – T cryocooler may be written as follows:

$$\mathrm{COP} = \frac{\eta_c \left[(h_1' - h_2) - (1-e)\,(h_1' - h_g) \right]}{T_2\,(s_1 - s_2) - (h_1 - h_2)}$$

Figure 14. Joule – Thomson cryocooler (refrigerator)
a) Compressor; b) Heat exchanger; c) J – T valve; d) Evaporator

The liquid in the evaporator of the J – T cryocooler evaporates at a constant temperature; therefore, the FOM for the J – T system involves the COP for the Carnot refrigerator (Eq. 12). Liquid nitrogen may be used as the refrigerant for the temperature range of ca. 65 – 115 K. The low temperature limit is set by the triple-point temperature for the refrigerant and by problems in maintaining the low vacuum pressure with reasonable mass flow rates. The high temperature limit is set by the critical point for the refrigerant. If the evaporator pressure is lowered below the triple-point pressure, nitrogen "snow" forms in the evaporator and the expansion valve is likely to become clogged. In addition, the heat transfer in the evaporator is degraded. If the evaporator pressure is increased above the critical pressure, no liquid forms on expansion through the J – T valve. If maintenance of a constant temperature in the evaporator is not a concern, the temperature range for the J – T cryocooler using nitrogen gas can be extended up to ambient temperature; however, other working fluids, such as freon compounds, are more effective at temperatures above ca. 200 K. The temperature in the evaporator can be controlled by regulating the pressure in the evaporator.

Miniature J – T cryocoolers have been built by using an adsorption compressor [24].

Large quantities of gas are adsorbed by an adsorbent. The material is then heated in a closed container to produce a high-pressure gas. The gas flows through the J – T portion of the system, and the return gas is adsorbed in a second adsorbent chamber, which is cooled. The cold compressor temperature is 150 K, and the hot compressor temperature is 470 K. A COP of 0.22 was reported for nitrogen gas absorbing energy at 77 K, which corresponds to a FOM of 0.64.

4.3. CVI Cold-Gas Refrigerator

In many applications, a constant-temperature source is not required; helium or neon may be used as the working fluid, and the gas need not be condensed to provide refrigeration. The CVI cold-gas refrigerator (see Fig. 15) is an example of this type of cryocooler [25]. This unit has been used to provide cooling for the cryopanels in space environmental simulation chambers, for recondensation of boiled-off hydrogen gas, and for other applications involving cooling in the 20 K temperature range. The working fluid for the CVI refrigerator is helium.

The helium gas is compressed in a rotary compressor (a), and after passing through a filter system to remove traces of oil from the compressor, the gas is cooled in a three-channel heat exchanger (b). The high-pressure stream is further cooled in a liquid-nitrogen-cooled precooler (c) and a cold heat exchanger (d). Trace impurities in the helium, such as carbon dioxide, are removed in an adsorption purifier in the liquid nitrogen bath. The gas then expands through an expander (e) before passing through the load heat exchanger (which replaces the evaporator in J – T systems). The CVI refrigerator uses highly effective, brazed aluminum plate-fin heat exchangers.

The refrigeration effect for the CVI refrigerator is given by

$$Q_A/q_m = h_7 - h_6 = (h_7 - h_5) + \eta_{ad}\,(h_5 - h_6')$$

Figure 15. CVI cold-gas refrigerator using helium gas as the working fluid
a) Helium compressor; b) Heat exchanger; c) Precooler; d) Heat exchanger; e) Expander; f) Load heat exchanger

where η_{ad} = adiabatic efficiency of the expander, and h'_6 = enthalpy for an isentropic expansion from point 5 to 6. The system can operate without the liquid nitrogen precooling; however, the refrigeration effect is reduced by a factor of ca. 3. The mass of liquid nitrogen precoolant required per unit mass of helium gas is given by

$$\frac{(q_{\mathrm{m}})_{\mathrm{N}}}{(q_{\mathrm{m}})_{\mathrm{He}}} = \frac{(h_2 - h_1) + (h_8 - h_4)}{h_{\mathrm{c}} - h_{\mathrm{a}}}$$

The liquid nitrogen precoolant bath helps overcome the ineffectiveness of the warm heat exchanger in the system.

4.4. Stirling Refrigerator

The Stirling cycle was originally developed in 1816 by Robert Stirling for use in a hot-air engine [26]. The first Stirling cycle refrigerator was described by Alexander Kirk in 1864 [27]. Workers at the Philips Co. in Eindhoven were instrumental in developing the refrigerator into a commercially viable system in 1953 [28]. Since then, several other organizations have designed Stirling refrigerators for cooling infrared thermal imaging systems, spacecraft instrument systems, and superconducting elements.

A schematic of the operating cycle for the Stirling refrigerator is shown in Figure 16. The Stirling cryocooler consists of a cylinder enclosing a power piston (c) and a displacer piston (a). The two chambers in the engine are connected through a regenerator (b), which is a critical component of the cryocooler.

Figure 16. Sequence of operations for the Stirling cycle refrigerator
A) Process 1 → 2; B) Process 2 → 3; C) Process 3 → 4; D) Process 4 → 1
a) Displacer piston; b) Regenerator; c) Power piston

The sequence of processes for the Stirling cycle refrigerator is as follows:

Process 1 → 2 (Fig. 16A). The working fluid (usually helium gas, although hydrogen or neon can also be considered) is compressed by the power piston while heat is rejected to cooling coils at the warm end of the cylinder. In the ideal case, this compression process is isothermal.

Process 2 → 3 (Fig. 16B). With the power piston approximately stationary, the gas is forced through the regenerator by the motion of

the displacer piston. The gas is cooled by heat exchange with the cold regenerator matrix. In the ideal case, this is a constant-volume process.

Process 3 → 4 (Fig. 16C). The gas is expanded by motion of both the power and the displacer pistons, while heat is absorbed from the low-temperature region at the cold end of the piston. Ideally, this process is isothermal.

Process 4 → 1 (Fig. 16D). The cold gas is forced back through the regenerator by the motion of the displacer, while the power piston remains approximately stationary. The gas is warmed nearly to ambient temperature by heat exchange with the regenerator matrix. Ideally, this heating process is a constant-volume process.

For the ideal Stirling refrigerator, the COP is the same as that of the Carnot refrigerator, i.e., the FOM is unity.

$$\mathrm{COP} = \frac{T_3}{T_1 - T_3}$$

Frictional energy dissipation, pressure drops through the regenerator, and the ineffectiveness of the regenerator all interact to reduce the COP of the actual refrigerator to ca. 0.35, depending on the temperature at the cold end of the cylinder. An excellent analysis of the operation of the actual Stirling cryocooler has been given [16, pp. 131 – 142]; a more exact numerical analysis is presented in [29]. The success of the Stirling cryocooler depends largely on the effectiveness of the regenerator. The regenerator commonly used has a matrix of fine wires that results in a large surface area and high regenerator effectiveness. The fraction of the ideal refrigeration effect that is wasted because of the regenerator ineffectiveness is given by

$$\frac{\Delta Q}{Q'_{\mathrm{A}}} = \frac{(1-e)\,[(T_2/T_3)-1]}{(\gamma-1)\ln(v_4 v_3)}$$

where γ = specific heat ratio, v = specific volume, and Q'_{A} = ideal heat transfer rate from the low-temperature region; the numerical subscripts refer to the processes listed above. If the following numerical values are used, the importance of the regenerator may be demonstrated. For $\gamma = 1.67$ (helium gas), $v_4/v_3 = 1.50$, $T_2 = 300$ K, and $T_3 = 78$ K,

$$\Delta Q/Q'_{\mathrm{A}} = 10.48\,(1-e)$$

Thus, if the regenerator effectiveness is 0.99, the cooling effect loss is 0.108, i.e., >10 % of the ideal refrigeration effect is wasted because of a 1 % decrease in the regenerator effectiveness.

4.5. Vuilleumier Refrigerator

The Vuilleumier (VM) refrigerator, first patented by Rudolph Vuilleumier in 1918 in the United States [30], is similar to the Stirling cryocooler, except that the VM refrigerator uses a thermal compression process instead of the mechanical compression process used in the Stirling system. A schematic of the VM refrigerator is shown in Figure 17.

Figure 17. Vuilleumier refrigerator
a) Hot cylinder; b) Regenerator; c) Displacer piston; d) Cold cylinder

In the VM cryocooler, heat is added from a high-temperature source to the gas in the hot cylinder (a), and the displacer piston (c_1) moves downward to maintain the temperature of the gas constant at T_{h} [31]. At the same time, near-ambient-temperature gas flows from the intermediate volume through the regenerator (b_1) to the hot volume. The displacer then moves upward to displace the gas from the hot volume to the intermediate volume. Heat is rejected from the gas in the intermediate volume to maintain the temperature constant at T_0. The motion of the cold piston (c_2) is approximately 90° out of phase with the motion of the hot piston. As the cold piston moves to the left, heat is absorbed

by the gas in the cold volume from the low-temperature source to maintain the gas temperature constant at T_1. At the same time, gas from the intermediate volume flows through the cold regenerator (b_2) to the cold volume. The cold displacer moves back to the right, and gas is displaced from the cold volume back to the intermediate volume.

The ideal COP for the VM cryocooler is given by

$$\mathrm{COP} = \frac{Q_c}{Q_h} = \frac{T_c\,(T_h - T_o)}{T_h\,(T_o - T_c)}$$

where the subscript c denotes the cold cylinder, h the hot cylinder, and o ambient temperature. The factors that contribute to reduction of the COP for the actual system include the following: (1) shuttle loss, caused by the mismatch between the displacer and the cylinder wall, (2) pumping loss, caused by the gas volume between the displacer and the cylinder wall, (3) heat transfer through the displacers from the warmer end to the cooler end, (4) heat transfer through the cylinder wall from the warmer end to the cooler end, (5) frictional energy dissipation between the cylinder wall and the displacer seals, and (6) losses because of the ineffectiveness of the regenerators. An advantage of the VM cryocooler is that the thermal input may be provided by isotope energy or solar energy. This makes the unit attractive for cryogenic cooling in long-term space exploration and in applications where mechanical vibration of the drive engine must be avoided [16, pp. 186 – 187].

4.6. Solvay Refrigerator

The Solvay refrigerator was originally developed in Germany in 1887 [32]. It was one of the first refrigerators planned for use in an air liquefaction system that had an expansion engine. However, Solvay's prototype system was unable to achieve temperatures <178 K. The system was not considered for cryogenic refrigeration until the late 1950 s, when Gifford and McMahon of A. D. Little constructed a Solvay refrigerator for cooling a miniature infrared detector system [33]. A schematic of the Solvay cryocooler is shown in Figure 18.

Figure 18. Solvay cryocooler
a) Compressor; b) Surge vessel (b_1 is at p_1, i.e., low pressure in the cycle, b_2 is at p_2, i.e., high pressure in the cycle); c) Inlet valve; d) Outlet valve; e) Regenerator; f) Seal; g) Displacer piston; h) Cylinder; i) Expansion space; j) Load heat exchanger

The system consists of a piston – cylinder arrangement (g) and (h) a regenerator (e), and a compressor (a) with inlet (c) and outlet (d) control valves. The cold part of the piston is at the lower end, whereas the upper portion of the cylinder operates at ambient temperature. The cylinder is constructed of thin-walled stainless steel tubing, and the piston is constructed of a low-conductivity plastic material so that heat conduction from the warm end to the cold is minimized. A sliding seal (f) is placed at the warm end of the piston to prevent leakage of the working gas from the system. Problems with operating a seal at cryogenic temperatures are avoided by placing the seal at the warm end. The piston generally fits quite loosely within the cylinder, with up to 0.5 mm clearance, except for the gas-tight seal at the warm end.

The regenerator uses punched copper disks or brass screens as the matrix. The screens or disks are separated by stainless steel wire spacers to prevent axial conduction along the regenerator.

The inlet and outlet control valves are coupled to the piston crankshaft so that the valves may be opened and closed at the appropriate time, depending on the position of the piston. These valves control the flow into and out of the expansion engine.

The sequence of operations for the Solvay cycle is as follows:

Process 1 → 2 (pressure buildup). With the piston at the bottom of the stroke, the inlet valve is opened, while the outlet valve remains closed. The high-pressure gas from the compressor flows through the regenerator, in which the gas is cooled; the system pressure increases.

Process 2 → 3 (intake stroke). With the inlet valve open and the outlet valve closed, the piston is raised to draw a volume of gas, which has been cooled by passage through the regenerator, into the cylinder.

Process 3 → 4 (expansion stroke). The inlet valve is closed and the piston continues to move toward the top dead center position. The gas within the cylinder expands (i) while doing work against the piston, and the gas temperature decreases to a low level.

Process 4 → 5 (exhaust process). When the piston reaches the top of its stroke, the outlet valve is opened and the gas pressure falls to the final minimum value. The exhaust value remains open as the piston moves back toward the bottom position to force the cold gas out of the cylinder through a load heat exchanger. Energy is absorbed from the external region, which is to be cooled during this process.

Process 5 → 1. The cold gas passes back through the regenerator, where it is warmed back to ambient temperature. The outlet valve is then closed, the inlet valve is opened, and the cycle is ready to be repeated.

The refrigeration effect for this cryocooler is given by

$$Q_{\mathrm{A}}/q_{\mathrm{m}} = \left(h_5 - h_4'\right) - (1-\eta_{\mathrm{ad}})\left(h_3 - h_4'\right)$$

where h_3 = enthalpy at the expander inlet, h_4' = enthalpy for an isentropic expansion from pressure p_3 to p_4, h_5 = enthalpy of the stream leaving the load heat exchanger, and η_{ad} = adiabatic efficiency for the expansion process between point 3 and point 4 (see process 3 → 4).

The *miniature Solvay cryocooler* described by GIFFORD and MCMAHON can maintain a temperature of 55 K with a single stage. The cylinder is a stainless steel tube having a 5-mm outside diameter, a 0.13-mm wall thickness, and a length of 51 mm. The piston is constructed of a linear base-laminated phenolic compound. The regenerator was actually contained within the piston in their design. The working fluid is helium gas, which varies in pressure between 0.345 and 1.725 MPa. The cool-down time for the unit is ca. 3 min.

4.7. Gifford – McMahon Refrigerator

A schematic of the Gifford – McMahon cryocooler is shown in Figure 19 [34]. This system differs from the Solvay refrigerator in that two spaces are used within the cylinder, and the piston does little work as it moves within the cylinder. The displacer piston simply moves the gas from one volume to the other during the cycle.

Figure 19. Gifford – McMahon refrigerator
a) Compressor; b) Surge vessel (b_1 is at p_1, b_2 is at p_2); c) Inlet valve; d) Outlet valve; e) Regenerator; f) Seal; g) Displacer piston; h) Cylinder; i) Upper expansion space; j) Lower expansion space; k) Load heat exchanger

The sequence of operations for the Gifford – McMahon cycle is as follows:

Process 1 → 2 (pressure buildup). With the displacer (g) at the bottom of the cylinder (h) and the outlet valve (d) closed, the inlet valve (c) is opened and the pressure within the cylinder is increased from the low pressure p_1 to the high pressure p_2. The volume of the lower expansion space (j) is practically zero during this process.

Process 2 → 3 (intake stroke). With the inlet valve open and the outlet valve closed, the displacer piston is moved from the bottom position to the top of the cylinder. This piston motion moves the gas that was originally in the upper (warm) expansion space (i) through the regenerator to the lower (cold) expansion space. Because the gas is cooled as it passes through the regenerator (e), its volume tends to decrease and

additional gas is drawn in through the inlet valve to maintain a constant pressure within the system.

Process 3 → 4 (pressure release and expansion). With the displacer at the top of the cylinder, the inlet valve is quickly closed and the outlet valve is slowly opened, thus allowing the gas within the lower expansion space to expand from pressure p_2 to the low pressure p_1. The gas that remains in the lower expansion space does work in forcing out the gas that leaves during this process; therefore, the temperature of the remaining gas drops. Ideally, the expansion takes place reversibly and adiabatically (isentropic expansion).

Process 4 → 5 (exhaust stroke). With the outlet valve open, the low-temperature gas is forced from the lower expansion space by moving the displacer down to the bottom of the cylinder. The cold gas flows through a heat exchanger (k) to absorb energy from the low-temperature source.

Process 5 → 1 The gas flows back through the regenerator, where it is warmed to ambient temperature, and the cycle is ready to be repeated.

The refrigeration effect for the Gifford–McMahon system is given by

$$Q_{\mathrm{A}}/q_{\mathrm{m}}=\eta_{\mathrm{ad}}\left[(q_{\mathrm{m}})_{\mathrm{e}}/q_{\mathrm{m}}\right]\left(h_5-h_4'\right)$$

where η_{ad}= adiabatic efficiency, for the expansion process from point 3 to point 4 (process 3 → 4), $(q_{\mathrm{m}})_{\mathrm{e}}$= mass of gas within the lower expansion space at the end of the expansion process, q_{m}= total mass compressed, h_4' = enthalpy for an isentropic expansion from point 3 to point 4, and h_5 = enthalpy of the stream leaving the heat exchanger. Because the volume of the cold expansion space remains essentially constant during the expansion process, the mass ratio may be calculated from the density ratio:

$$(q_{\mathrm{m}})_{\mathrm{e}}/q_{\mathrm{m}}=\varrho_4'/\varrho_3$$

The Gifford–McMahon refrigerator has several advantages over Claude-type refrigerators, which also use an expander. In the Gifford–McMahon cryocooler, all valves and seals operate at ambient temperature; therefore, problems with low-temperature seals and valves are eliminated. Problems with leakage around the piston seals are reduced because the viscosity of a gas near ambient temperature is higher than the gas viscosity at cryogenic temperatures. Whereas low-temperature operation requires special dry sealing rings, the Gifford–McMahon system allows the seals to be constructed of conventional materials.

The Gifford–McMahon refrigerator uses a regenerator instead of the heat exchangers employed in the Claude and J–T refrigerators. In general, regenerators are less expensive than heat exchangers, and the regenerator can be constructed with a larger heat transfer surface area per unit volume, which is important for miniature systems. Because of the back-and-forth motion of the gas through the regenerator, impurities deposited during the intake process are swept out of the system during the exhaust stroke; thus, problems with impurity buildup are minimized with the use of the regenerator.

The Gifford–McMahon system is also well-suited for multistaging [35]. In some cryogenic systems, refrigeration is required at intermediate temperatures, for example, to cool radiation shields around the unit. In this case the system can be operated with two stages, one for cooling the shields at 77 K, for example, and the other stage to provide the low-temperature refrigeration at 20 K. In addition, a multistage refrigerator generally has a higher thermodynamic performance than a single-stage unit. A typical two-stage Gifford–McMahon refrigerator is shown in Figure 20.

Figure 20. Two-stage Gifford–McMahon refrigerator
a) Regenerator; b) Seals; c) Displacer piston; d) Load heat exchanger

The principal disadvantage of the Gifford–McMahon cryocooler is that the COP is inherently smaller than that of the Claude cryocooler operating between the same pressure limits, because only a fraction of the total mass compressed in the Gifford–McMahon system is expanded during the expansion process.

4.8. Magnetic Refrigerators

When a liquid or gas is used as the working fluid in a refrigerator, the operating temperature is limited to values above ca. 1 K. All materials other than ordinary helium (^{4}He) and the helium isotope ^{3}He are in the solid phase at temperatures below 1 K. The low temperature that can be attained with boiling helium is determined by the vapor pressure of the helium. At 1 K, the vapor pressure of ^{4}He is 16 Pa, and the vapor pressure of ^{3}He is 1180 Pa. At 0.5 K, the vapor pressures are 1.9 mPa (^{4}He) and 22.2 Pa (^{3}He) [36]. Clearly, a refrigerator operating at these low pressures in the evaporator is impractical for relatively large capacities because of the size of the flow passages required for even moderate mass flow rates.

History. Giauque and Debye independently suggested a method to break this "temperature barrier" in the 1920 s [37, 38]: A paramagnetic material could be used instead of a liquid or gas as the working medium to reach temperatures <1 K, because the entropy associated with the electron-spin system becomes much larger than the entropy associated with the lattice vibrations. In 1933 Giauque and MacDougall (who won a Nobel prize for the feat) were able to verify the magnetic cooling concept experimentally [39]. They reached a temperature of 0.53 K with gadolinium sulfate after demagnetizing from a field of 0.8 T and an initial temperature of 3.5 K. DeHaas and coworkers attained a temperature of 0.27 K 2.5 weeks later by demagnetizing CeF_3 from 2.8 T at 1.3 K [40].

The principle of cooling by adiabatic demagnetization is similar to the cooling effect produced when a gas expands isentropically. When a gas is compressed isothermally, the entropy of the gas decreases because the order of the molecules increases (the atoms occupy a smaller volume with no increase in random molecular velocities). If the high-pressure gas is expanded reversibly and adiabatically, the entropy of the gas remains constant; therefore, the temperature of the gas decreases to offset the increase in disorder produced by moving the molecules farther apart.

A paramagnetic material produces order (or reduces entropy) differently. In the absence of a magnetic field, the dipoles of the magnetic material are more or less randomly arranged because of the disturbing effect of random thermal vibrations. If an external magnetic field is applied to the material while the material temperature is maintained constant, the entropy or disorder of the material decreases, because the dipoles tend to line up with the magnetic field. If the magnetic field is reversibly and adiabatically removed, the temperature of the paramagnetic material decreases to maintain constant entropy. This process, which is called *adiabatic demagnetization*, is the basis for the magnetic refrigerator used to reach temperatures down to 0.1 K.

A schematic of the basic magnetic refrigerator is shown in Figure 21. Lines of constant magnetic field strength replace the constant pressure lines on the temperature–entropy diagram for the cycle. The refrigerator consists of the following: a working salt (e), such as iron ammonium alum, which is the cooling medium for the refrigerator; a reservoir salt (f), which acts as a "thermal flywheel" to smooth out temperature fluctuations in the space to be cooled; thermal valves (b) to control heat transfer to and from the working salt; and solenoids (c and d), which are used to apply the required magnetic fields to the working salt and the thermal valves.

The sequence of operations for this refrigerator is as follows:

Process $1 \rightarrow 2$ (corresponds to the isothermal compression process in the Carnot cycle). With the upper thermal valve open (heat transfer is allowed) and the lower thermal valve closed (no heat transfer), the magnetic field around the working salt is increased from 0.14 to 0.72 T. Heat transfer occurs between the working salt and the liquid helium bath to maintain a constant temperature in the working salt. The working salt is thermally isolated from the reservoir salt during this process.

Process $2 \rightarrow 3$ (corresponds to the reversible adiabatic expansion process in the Carnot cycle).

Figure 21. Magnetic refrigerator
A) Schematic diagram: a) Liquid helium; b) Thermal valve; c) Valve magnet; d) Main magnet; e) Working salt; f) Reservoir salt; g) Space to be cooled
B) Thermodynamic diagram for the cycle

Both thermal valves are closed so that the working salt is thermally isolated (adiabatic process) and the main magnetic field is reduced from 0.72 to 0.10 T. The temperature of the working salt decreases to ca. 0.16 K from an initial temperature of 1.15 K.

Process $3 \rightarrow 4$ (corresponds to the isothermal heat addition process in the Carnot cycle). The thermal valve between the working salt and the reservoir salt is opened to allow heat exchange between the two materials, and the magnetic field around the working salt is reduced to zero. Heat is transferred to the working salt from the reservoir salt to maintain constant temperature.

Process $4 \rightarrow 1$ (corresponds to the reversible adiabatic compression process in the Carnot cycle). The working salt is again thermally isolated by closing both thermal valves, and the magnetic field around the working salt is increased from 0 to 0.14 T. The temperature of the working salt increases to the initial value, and the cycle has been completed.

The energy absorbed as heat from the low temperature region (the reservoir salt) in the ideal case is given by Equation (15)

$$Q_{\mathrm{A}} = q_{\mathrm{m}} T_3 \left(s_4 - s_3\right) \tag{15}$$

where q_{m} = mass of the working salt and s = magnetic entropy of the working salt. Ideally, the heat rejected from the working salt to the helium bath is given by

$$Q_{\mathrm{R}} = q_{\mathrm{m}} T_1 \left(s_2 - s_1\right) = -q_{\mathrm{m}} T_1 \left(s_4 - s_3\right)$$

The net magnetic work done on the working salt is equal to the net heat transfer for a cycle; therefore,

$$W_{\mathrm{net}} = q_{\mathrm{m}} \left(T_1 - T_3\right) \left(s_4 - s_3\right) \tag{16}$$

Equations (15) and (16) show that the COP of the ideal cycle is the same as that of a Carnot cycle. Irreversibilities reduce the performance of the actual refrigerator below that of the ideal system. For example, at a source temperature of 0.4 K, the Daunt – Heer – Barnes refrigerator [41] has a refrigeration capacity of 27.5 μW, whereas the refrigeration capacity of the ideal system operating under the same conditions is 34.4 μW. At a source temperature of 0.3 K, the refrigeration capacity is 14.3 μW, compared with 25.8 μW for the ideal system.

One of the advantages of the magnetic refrigerator is that its operation is not dependent on the presence of a gravitational force; thus, the system can operate effectively in a zero-gravity environment. Infrared bolometers in space systems have been cooled by magnetic refrigerators.

One of the critical components of the magnetic refrigerator is the thermal valve or "switch." In the Daunt – Heer – Barnes refrigerator, a thin lead strip is used as the thermal valve. At a temperature of 1 K, the thermal conductivity of lead in the superconducting state is ca. 0.025 times the thermal conductivity of the material in a normal state; at 0.2 K, the ratio is ca. 0.010. Thus, the valve can be "closed" (little heat transfer through the valve) by decreasing the magnetic field around the valve to drive the lead into the superconducting state. The valve can be "opened" by increasing the magnetic field so that the lead strip returns to the normal state. Changes in magnetic field around the thermal valves are accomplished with small "valve magnets" around the lead strips. Other types of thermal switches have been tried, but they are generally not as effective as the superconducting switch. For example, mechanical switches allow zero thermal leakage when contact is broken; however, energy is dissipated when the contact is made or broken, and this energy dissipation cannot be tolerated in the region below 1 K.

Magnetic wheel refrigerators have been constructed for use in the temperature range between 2 and 10 K [42, 43]. A schematic of this type of refrigerator is shown in Figure 22.

Figure 22. Schematic of the magnetic wheel refrigerator a) Wheel; b) Pump; c) Heat exchanger

Helium gas enters the wheel (a) in the low-field region at a temperature of T_h and is cooled to T_l by heat exchange with the magnetic material. The wheel is constructed of granules of gadolinium sulfate for improved heat exchange with the helium gas. The gas leaves the low-field region of the wheel and flows through a heat exchanger (c_1) in which the cooling load is absorbed by the helium gas. The gas enters the high-field region of the magnetic wheel at temperature ($T_c + \Delta T$), where ΔT is the intrinsic temperature change of the magnetic material as it moves from the low-field region to the high-field region. The helium gas is warmed in the high-field region to a temperature ($T_h + \Delta T$) by heat exchange with the magnetic material. The helium gas finally flows through a warm heat exchanger (c_2), in which heat is rejected to the heat sink, and the gas is cooled back to temperature T_h.

In a working model of the magnetic wheel refrigerator, a 3-T magnetic field was used in the high-field region, and the rotational speed of the 150-mm diameter wheel was 6 rpm. A temperature difference of 7 K was maintained with a 500-W thermal load on the cold side.

4.9. Dilution Refrigerator

One of the most widely used refrigerators for the temperature range between 0.005 and 1 K is the ^{3}He – ^{4}He dilution refrigerator. This is a relatively new development in cryogenic technology.

History. In 1951 H. London suggested that cooling could be achieved by dilution of liquid ^{3}He with superfluid liquid ^{4}He [44]. Little interest existed for developing a practical refrigerator at that time, because the phase separation of ^{3}He – ^{4}He mixtures had not been discovered. London [45] presented a practical design for the dilution refrigerator in 1962 after the phase separation phenomenon was discovered experimentally by Walters and Fairbank in 1956 [46]. The first dilution refrigerator was constructed by Das and coworkers [47] at the University of Leiden in 1965. In 1966 Hall and associates [48] and Neganov and others [49] in Russia constructed dilution refrigerators that achieved temperatures between 0.025 and 0.060 K. Commercial dilution refrigerators can continuously reach 0.005 K.

The entropy of pure liquid ^{4}He below 1 K is quite small and varies proportionally with T^3. On the other hand, the entropy of liquid ^{3}He below 1 K is somewhat larger and is proportional

to T. Thus, the ^{4}He in a ^{3}He – ^{4}He mixture contributes little to the total entropy of the mixture below 1 K.

Because ^{3}He has a higher entropy in the dilute phase mixture (dilute in ^{3}He), an amount of heat $Q = T \Delta S$ is absorbed for each mole of ^{3}He that passes from the pure phase to the dilute phase mixture in a reversible manner. The main problem is how to mix the two materials in a reversible manner. Fortuitously, nature provides a reversible mechanism for the dilution: the helium mixture separates into a dilute phase and a concentrated phase at temperatures below 0.86 K. The concentrated phase is less dense than the dilute phase and, therefore, floats on top of the dilute phase mixture. The concentrated phase is a normal fluid, whereas, the ^{4}He component in the dilute phase is a superfluid. Because the two phases are in thermodynamic equilibrium, ^{3}He can move reversibly from the low-entropy concentrated phase to the high-entropy dilute phase, analogous to the evaporation of liquid molecules into the vapor phase above the liquid. In addition, the mole fraction of ^{3}He in the dilute phase at absolute zero is not zero, but instead approaches a finite value of $x_D = 0.064$. This fact means that at low temperature the high-entropy phase has a particle density that is high enough to permit relatively high flow rates for the ^{3}He, which is important in the design of a practical refrigerator.

One other property that permits design of a practical dilution refrigerator is the fact that ^{3}He has a much higher vapor pressure than ^{4}He at the same temperature. This means that the vapor in equilibrium with the liquid phase is practically pure ^{3}He for temperatures below 1 K. A schematic of a ^{3}He – ^{4}He dilution refrigerator is shown in Figure 23.

The gas (which is practically pure ^{3}He) is compressed in a vacuum pump (a) from ca. 4 Pa to 4 kPa. The gas is cooled in a heat exchanger (b_1) and a liquid helium bath (c_1) at 4.2 K, and is then condensed in a liquid helium bath (c_2) at reduced pressure and a temperature of ≤ 1.2 K. The liquid ^{3}He is expanded through a capillary tube constriction (d) and is cooled further in the still (e), which operates at ca. 0.6 K. The liquid is further cooled in a heat exchanger (b_2) before it enters the mixing chamber (f), where ^{4}He is mixed with the ^{3}He at temperatures between 0.050 and 0.005 K.

Figure 23. ^{3}He – ^{4}He dilution refrigerator
a) Vacuum pump; b) Heat exchanger; c) Helium bath; d) Constriction; e) Still; f) Mixing chamber: f_1 is concentrated mixture (85 % ^{3}He), f_2 is dilute mixture (6.4 % ^{3}He)

The liquid in the mixing chamber separates into two liquid phases, a less dense concentrated ^{3}He mixture (f_1) and a more dense diluted ^{3}He mixture (f_2). The ^{3}He molecules diffuse from the concentrated phase to the dilute phase, with heat being absorbed during this process. The dilute mixture returns through the heat exchanger to the still, where heat is added to evaporate the ^{3}He from the mixture. The mole fraction of ^{3}He in the liquid in the still is ca. 1 %, and the composition of the vapor is between 95 and 98 % ^{3}He.

The refrigeration effect of the dilution refrigerator is given by

$$Q_A = (q_v)_{He} (h_m - h_i)$$

where $(q_v)_{He}$ = molar flow rate of ^{3}He, h_m = molar enthalpy leaving the mixing chamber, and h_i = molar enthalpy of the ^{3}He entering the mixing chamber. For temperatures below ca.

0.04 K, the enthalpies may be approximated by Equations (17) and (18) [50]:

$$h_m = C_1 T_m{}^2 \text{ where } C_1 = 94\,\mathrm{J\,mol^{-1}\,K^{-2}} \quad (17)$$

$$h_i = C_2 T_i{}^2 \text{ where } C_2 = 12\,\mathrm{J\,mol^{-1}\,K^{-2}} \quad (18)$$

One of the more critical components of a dilution refrigerator is the heat exchanger between the mixing chamber and the still, which must have a high effectiveness; otherwise the system will not work. From Equations (17) and (18), the maximum temperature ratio (corresponding to zero heat transfer in the mixing chamber) is $T_1/T_m = 2.80$. For a value of $T_m = 0.040$ K, the largest value for T_1 for a positive refrigeration effect is 0.112 K, which yields a maximum temperature difference at the cold end of the exchanger of $(T_1 - T_m) = 0.072$ K. Heat exchangers with large surface areas per unit volume have been developed using sintered metal elements within the flow passages [51].

5. Components of Liquefiers and Cryocoolers

The three important subassemblies of liquefaction systems and cryogenic refrigerators are the heat exchanger or regenerator, the compressor, and the expander. Other components in these systems include the J – T valve, filters, and purifiers. However, this chapter addresses only the first three items.

5.1. Cryogenic Heat Exchangers

One of the most critical components in any liquefaction system or cryogenic refrigerator is the heat exchanger. In conventional systems using heat exchangers, such as regenerative gas turbine units, the system can operate satisfactorily with a heat exchanger having an effectiveness (e) as low as 0.50. However, a heat exchanger effectiveness of 0.85 or higher is required if the liquefier is to produce liquid at all. For example, nitrogen has the following enthalpy values [52]:

$h_1' = 462.15$ J/g at 300 K and 0.101 MPa
$h_2 = 431.50$ J/g at 300 K and 20.3 MPa
$h_g = 228.66$ J/g at 0.101 MPa and saturated vapor.

Using Equation 5 with zero heat inleak from ambient, the minimum heat exchanger effectiveness (e_{min}) for the basic Linde – Hampson liquefier of J – T cryocooler is found to be

$$e_{min} = 1 - \frac{(462.15 - 431.50)}{(462.15 - 228.66)} = 0.869$$

The effectiveness of the heat exchanger must be higher than 0.869 in this example for the liquefier to work. The importance of the heat exchanger may also be demonstrated by noting that the liquid yield for a Linde – Hampson system with a perfect heat exchanger is 0.0708, whereas for a heat exchanger with an effectiveness of 0.99, the liquid yield for the Linde – Hampson liquefier is decreased to 0.0658. A reduction of the effectiveness by 1 % results in a 7.1 % reduction in the liquid yield.

5.1.1. Types of Cryogenic Heat Exchangers

Many different types of heat exchangers (also called *recuperators*) are used in cryogenic liquefaction and refrigeration systems. The units may be classified as follows:

1) tubular exchangers
2) plate-fin exchangers
3) perforated-plate exchangers

Tubular Exchangers. Four basic tubular exchangers are shown in Figure 24. The simplest form of tubular exchanger is the *double-pipe or concentric-tube heat exchanger* (Fig. 24A, see next page). This was the unit used by Linde in his original liquefier. The fluids are in counterflow, with the high-pressure warm stream (a) in the inner tube and the low-pressure cold stream (b) in the annular region between the two tubes. To conserve space, the concentric tubes are wound in a large helix, and the unit is insulated to reduce heat transfer from the surroundings.

Concentric-Tube Exchanger with Wire Spacer. The performance of the concentric-tube exchanger may be improved by wrapping a wire or plastic spacer around the inner tube (Fig. 24B). This spacer tends to maintain a concentric relation of the inner tube with the outer tube and forces the low-density gas in the annular space (b) to follow a long helical path,

thereby increasing the gas velocity and improving the heat transfer coefficient.

Figure 24. Cryogenic heat exchangers
A) Linde concentric-tube exchanger; B) Concentric-tube exchanger with wire spacer; C) Multiple-tube exchanger; D) Bundle-tube exchanger
a) High-pressure stream; b) Low-pressure stream; c) Intermediate-pressure stream

Several tubes may be contained inside a larger tube to form a *multiple-tube exchanger* (Fig. 24C). This unit can be used in the Linde dual-pressure system for the three-channel heat exchanger. In this case, the high-pressure stream (a) flows in one of the smaller tubes, the intermediate-pressure stream (c) flows in the other smaller tubes, and the low-pressure stream (b) flows in the space between the small tubes and the larger enclosing tube. Spiral windings, spacers, or longitudinal fins are used to locate the small tubes within the larger tube.

The *bundle- or cluster-tube heat exchanger* is formed by brazing or soldering several tubes around a central tube. The high-pressure stream generally flows in the central tube (a), while the low-pressure stream flows in the tubes (b) clustered around the center tube.

Giauque – Hampson Heat Exchanger. The classic heat exchanger used for medium- to large-scale cryogenic liquefiers is the Giauque – Hampson type shown in Figure 25.

Figure 25. Giauque – Hampson heat exchanger
a) Insulation; b) Close-fitting sheath; c) Spiral-wound tubes; d) Punched spacer; e) Cylindrical mandrel

One or more coils of thin-walled stainless steel, aluminum, or copper tubes (c) are wound onto a low-conductivity mandrel (e), such as a stainless steel cylinder. A close-fitting sheath (b) of the same low-conductivity material is placed around the coil, and insulation (a) is added on the outside. The high-pressure stream flows inside the small tubes, while the low-pressure stream flows across the outside of the helical coil of small tubes between the inner mandrel and the outer sheath.

Uniform tube spacing is important in the construction of the Hampson heat exchanger; otherwise, the low-pressure gas tends to follow the path of least frictional resistance (through the widest spacing), and the flow is distributed unevenly. An important contribution to solve the spacing problem was made by Giauque at the

University of California in introducing *punched brass spacers* [53].

A thin strip of cellulose acetate was placed between the spacer and the tube as the coil was being wound. After winding was complete, the acetate was dissolved by acetone. Several layers of tubes were used to provide many parallel paths for the low-pressure fluid, thereby reducing the overall pressure drop on the low-pressure side. The length of the path of the high-pressure fluid inside the tubes was made constant by adjusting the pitch of the tube helix from layer to layer. Heat exchangers of this type are commonly called Giauque – Hampson exchangers.

Collins Heat Exchanger. A novel extended-surface heat exchanger design developed by Collins [54] and marketed by the Joy Manufacturing Co., Michigan City, Ind., is shown in Figure 26. This was the heat exchanger used by Collins in his helium liquefaction system (see Section 3.7).

Figure 26. Collins heat exchanger
a) Concentric copper tubes; b) Edge-wound copper helix

The exchanger consists of several concentric copper tubes (a) with a close coiled helix of edge-wound copper ribbon (b) in the annular space between the tubes. The helix is soft-soldered to both sides of the annular space in which it is wound. The copper helix acts as a fin or extended surface to increase the heat transfer surface area of the annulus. These heat exchangers have been manufactured with as many as ten different flow passages.

Plate-Fin Exchangers. The plate-fin heat exchanger (an example is shown in Fig. 27) consists of stacks of alternating layers of corrugated die-formed metal sheets, i.e., fins (a), between thin metal sheets or plates (b). The edges of each layer are sealed with bars (c), and the flow passages formed within the corrugations are terminated with headers at each end of the stack. Crossflow, counterflow, or multipass arrangements can be constructed with the individual sandwiches. This type of heat exchanger has the advantage that a high surface area: volume ratio may be achieved (a compact arrangement). For example, as much as 1475 m^2 of heat transfer surface per cubic meter of exchanger volume may be attained with a plate-fin exchanger.

Figure 27. Plate-fin heat exchanger
a) Corrugated fin; b) Metal sheets; c) Bars

Perforated Plate Exchanger (Fig. 28) [55]. This exchanger consists of several parallel perforated plates (b) with spacers (a) between the plates. The plates are made of high-conductivity metal, such as copper or aluminum; the spacers are made of a low-conductivity plastic. The spacers are bonded to the plates to provide sealing between the high- and low-temperature streams and to minimize longitudinal conduction in the exchanger. Heat exchange between the two fluid streams occurs by lateral conduction through the copper or aluminum plates.

The diameter of the perforations can be made quite small so that a large heat transfer surface area per unit volume can be attained. The disruption of the flow between each plate results in high

heat transfer coefficients (and high friction factors); therefore, highly effective heat exchangers of this type can be constructed at relatively low cost.

Figure 28. Perforated plate heat exchanger
a) Plastic spacer; b) Perforated metal plate

5.1.2. Heat Exchangers for Dilution Refrigerators

Heat exchangers for use in the dilution refrigerator system present special thermal problems because of the large thermal boundary resistance between helium and a solid surface at very low temperatures. This thermal resistance, called the *Kapitza resistance*, is inversely proportional to T^3, so the resistance can be quite large in the 0.01 K temperature range.

The *Frossati heat exchanger*, developed for a dilution refrigerator, is shown in Figure 29 [51].

Figure 29. Frossati heat exchanger for a ^{3}He – ^{4}He dilution refrigerator
a) Separator; b) Sintered silver powder; c) Rectangular channel

The heat exchanger consists of flow passages separated by Cu – Ni foil (a), which is silver-plated and coated with a silver powder (particle diameter 1 μm). The coating is placed between two layers of sintered silver powder (b), which are covered by rectangular channels (c). The sintered metal coating on the separator provides a large surface area per unit volume, which reduces the Kapitza resistance. The liquid helium mixture flows through the rectangular channel, instead of through the sintered metal, so the pressure drop through the heat exchanger is not excessive.

The Frossati heat exchanger uses a sintered metal coating thickness of ca. 1 mm. The flow passages vary in size from 12.2 m^2 (dilute side) and 5.0 m^2 (concentrated side) at the cold end of the exchanger down to 4.0 m^2 (dilute side) and 1.6 m^2 (concentrated side) at the warm end. The heat exchanger is 1.040 m long and is wound in a spiral to conserve space. A low temperature of 0.002 K is achieved continuously with this refrigerator.

Sintered metal powder heat exchangers represent the present state of the art for dilution refrigerator heat exchangers and are used in commercial refrigerators that produce 0.005 K continuously.

5.1.3. Heat Exchanger Design Problems

Three problems may become acute in designing heat exchangers for cryogenic systems:

1) the effect of variable fluid properties, in particular variation of specific heat
2) the effect of longitudinal conduction
3) the effect of uneven distribution of flow

In many conventional heat exchanger design situations, the specific heats of the two fluids may be treated as essentially constant. For gases such as hydrogen in the cryogenic temperature range, the specific heat may vary significantly, and this variation can cause a *thermal pinch* effect within the heat exchanger.

Table 4 presents data on the temperature distribution in a gaseous helium – gaseous hydrogen counterflow heat exchanger operating between 50 and 250 K for the hydrogen stream and between 60 and 260 K for the helium stream. The mass flow rate of the hydrogen stream is 1 kg/s, and the mass flow rate of the helium stream is 2.425 kg/s. The specific heat of the hydrogen gas is 10.55 kJ $kg^{-1}K^{-1}$ at 50 K, and 14.04 kJ $kg^{-1}K^{-1}$ at 250 K, which corresponds to a 40 % increase in the specific heat through the exchanger. If the specific heats of the gases are constant, the log-mean-temperature-difference (LMTD) for the exchanger is 10 K However,

because of the specific heat variation, the temperature difference (ΔT) becomes as small as 3.1 K in the middle of the heat exchanger, and the actual LMTD is only 4.92 K. Thus, the actual heat transfer surface area that is required is about two times that calculated assuming constant specific heats.

Table 4. Temperature in a gaseous hydrogen – gaseous helium heat exchanger

Temperature of hydrogen (T_{H_2}), K	Temperature of helium (T_{He}), K	ΔT *
50	60.0	10.0
70	76.9	6.9
90	95.6	5.6
110	114.9	4.9
130	133.6	3.6
150	153.1	3.1
170	173.5	3.5
190	194.5	4.5
210	215.9	5.9
230	237.8	7.8
250	260.0	10.0

* $\Delta T = T_H^e - T_{H_2}$

The problem of "thermal pinch" may be alleviated by "unbalancing" the heat exchanger by increasing the hydrogen gas flow (if possible). Alternatively the helium gas flow can be decreased by bleeding off a portion of the flow at some intermediate point in the exchanger.

Longitudinal heat conduction along the walls of conventional heat exchangers is usually not a serious problem, because of the great length of the heat exchanger. Miniature cryogenic refrigerators can use heat exchangers that are as short as 50 mm. In addition, the effect of longitudinal conduction is most severe for a heat exchanger that is very highly effective.

One solution to the problem of longitudinal conduction is the use of thin-walled tubes of a relatively low-conductivity material (stainless steel). The tubes are coupled intermittently by a plating of a high thermal conductivity material (silver solder) between the tubes [56]. The high-conductivity material allows good heat transfer between the tubes, and longitudinal conduction is reduced by the thermal breaks between the sections of plating.

Many cryogenic heat exchangers have several short parallel flow passages for one or both fluid streams, instead of a single long flow passage for each stream. Ideally, the flow divides equally among the parallel flow passages; in practice, however, assurance of equal flow in each channel is not always possible because of differences in manufacturing tolerances. This results in a higher flow rate in the flow passages of smaller frictional resistance. The problems caused by uneven flow distribution are more severe for highly effective heat exchangers, such as the cryogenic heat exchangers.

The effect of uneven flow distribution in cryogenic heat exchangers has been analyzed [57]. For a heat exchanger with a design effectiveness of 0.995, uneven distribution of flow can reduce the effectiveness for the heat exchanger in operation to a value of only 0.95.

One technique for solving the problem of uneven flow distribution uses flow constrictions in the middle of the heat exchanger on the warm side [58]. If the temperature of the warm fluid increases because of a higher flow rate in the passage, the constriction presents a higher flow resistance, thereby reducing the warm fluid stream flow through that passage and balancing the flow.

5.1.4. Regenerators

In ordinary heat exchangers, the two fluids exchanging energy are separated by a solid surface (e.g., tube wall, plate). In a regenerator, the two fluids occupy the same space alternately, while the energy to be transferred is stored and released from the regenerator packing material or matrix. The temperature of the fluid within the regenerator and the temperature of the regenerator matrix are functions of both position within the regenerator and time of operation. As a result, the performance of the regenerator is a function of the mass of the matrix, the specific heat of the matrix material, and the frequency of switching of the flow through the regenerator.

The regenerator in a cryogenic system consists of a matrix material contained within a cylinder. For continuous operation, pairs of regenerators are usually used so that the matrix in one unit can be heated while the matrix in the other unit is being cooled. Various materials have been used for the matrix, including small metal spheres, metal wires or strips, punched copper disks, and layers of small-diameter, woven wires.

The main *advantages* of regenerators over ordinary heat exchangers (recuperators) are as follows:

1) A much larger heat transfer surface area per unit volume can be achieved for the regenerator. As much as 4000 m^2 of surface area per cubic meter of volume can be obtained in a regenerator, compared with 1475 m^2/m^3 for a compact plate-fin heat exchanger.
2) The regenerator tends to be self-cleaning because of the periodic flow reversal. Impurity buildup problems are not nearly as severe in a regenerator as those in ordinary heat exchangers.
3) Regenerators are generally simpler to fabricate, so the regenerator tends to cost less than a heat exchanger for the same heat transfer duty.

The main *disadvantage* of the regenerator is that some mixing of the warm and cold streams occurs during the switching process. In addition, some means must be provided for switching the flow from one regenerator to the other in the regenerator pair.

5.2. Compressors

The compressor is an important component of all liquefaction and refrigeration systems because (1) it represents a significant fraction of the total initial capital cost of the unit, (2) its power input accounts for a large portion of the system operating costs, and (3) it is usually the component that determines the reliability of the system. Compressors used in cryogenic systems are classed as either reciprocating compressors or rotary compressors.

Reciprocating Compressors. Reciprocating compressors are generally more massive and operate at slower speed (up to 3000 rpm) than rotary compressors. The reciprocating units are used in systems requiring high pressure (4 – 20 MPa) and relatively low flow rate (<300 t/d). They are easily adapted to situations in which the load changes suddenly.

The compression process for reciprocating compressors is polytropic because the gas cools in the cylinder during compression. Two stages of compression with intercooling and aftercooling can be used for pressure ratios ranging from up to 8 to 10. For higher pressure ratios, three or four stages can be used to limit the temperature of the gas at the end of the compression process.

Compressors used in cryogenic systems generally operate at ambient temperature; thus, they are similar in design to compressors used for any gas compression service, with one important modification. Cryogenic compressors must be designed to reduce leakage around seals and to reduce contamination of the gas being compressed. One of the primary contaminants is the oil used to lubricate seals in the compressor piston. In compressors lubricated with oil, some provision must be made to separate the entrained oil from the gas. Steel wool or glass wool filters are used to remove liquid oil droplets, and refrigerated adsorption units are used to remove oil vapor.

Some compressors are operated without oil lubrication to avoid the problem of contamination of the gas being compressed. Older units used carbon piston rings, sometimes filled with a metal powder reinforcement. However, when the dew point of the water vapor in the gas is less than −30 °C, the carbon piston ring is unsuitable because of changes in the surface chemistry of the carbon. Without the presence of a little moisture, the carbon behaves as an abrasive material.

In current dry-lubricated compressors, polytetrafluoroethylene (PTFE) piston rings are used. To improve the wear characteristics and to allow better removal of the frictional energy dissipation, the PTFE rings are usually reinforced with a hard filler of a metal powder, such as brass or copper. Glass-filled PTFE rings (known as Rulon-A) have been used with good results.

The following factors contribute to the compressor efficiency being less than 100 %:

1) *Nonisothermal Compression.* Because of the relatively small surface area available for heat transfer in the compressor piston, the compression process is polytropic, with a polytropic exponent of ca. 1.3 – 1.4 for compression of diatomic gases.
2) *Valve Losses.* Pressure drops occurring across the inlet and outlet valves reduce the actual pressure ratio of the gas within the compressor cylinder.
3) *Piston Friction.* Frictional energy dissipation in the piston seals, bearings, etc. increases the required power input to the compressor.

Rotary Compressors. Rotary compressors are generally smaller and operate at higher speed

than reciprocating units. The rotary units are more sensitive to sudden changes in load; they are either axial flow, centrifugal flow, or rotary screw compressors.

Axial flow compressors have several stages of compression because the practical pressure ratio for each stage is relatively small. Intercooling is required, along with aftercooling, to limit the temperature of the gas being compressed. Because of the small surface area within the compressor flow passages, the compression process is practically adiabatic, but not reversible.

Centrifugal flow compressors involve a simple construction with a single rotating disc or impeller for each stage of compression. The limiting pressure ratio across each stage is 4 : 1, so multistage units must be used to achieve pressures >400 kPa. Centrifugal flow compressors also require intercooling and aftercooling to limit the temperature of the gas being compressed. In air liquefaction plants, multistage centrifugal compressors have been used to compress air to pressures of 4.0 – 5.5 MPa at flow rates <500 t/d.

Rotary screw compressors are finding increased application in cryogenic systems. The rotary unit consists of two or more cylindrical rotors with multiple helical lobes that mesh as the rotors turn. A volume of gas is trapped between the lobes and is compressed as the volume of the space decreases. The rotors are lubricated with oil sprayed onto the rotors at the low-pressure end of the compressor.

Some of the factors that contribute to the efficiency of the rotary compressor being less than 100 % include

1) *Nonisothermal Compression.* The compression process is almost adiabatic, rather than isothermal. More work is required to compress a gas adiabatically than for isothermal compression.
2) *Disk Friction.* For centrifugal flow compressors, frictional energy is dissipated between the rotor and the gas in the space between the rotor and the housing.
3) *Impeller Losses.* For both axial flow and centrifugal flow compressors, frictional energy dissipation and flow separation occur within the blade flow passages and reduce compressor efficiency.
4) *Exit Losses.* The kinetic energy of the stream leaving the last stage is dissipated and results in additional energy loss.

5.3. Expanders

The expanders used by Claude (see Section 3.5) were basically steam engines modified to operate with air instead of steam. Initially, Claude attempted to liquefy the gas within the engine and to use the liquid air as a lubricant [59]. This proved unsuccessful because of the low viscosity of liquid air and excessive heat transfer; thus, he finally used a leather cup as the piston seal.

In 1912 Heylandt improved the efficiency of expanders by using the crowned piston concept (Fig. 30) [16, p. 325].

Figure 30. Piston used in the expander in the Heylandt liquefaction system
a) Cylinder; b) Expansion space; c) Low-conductivity cap; d) Packing ring; e) Sealing piston; f) Piston rod; g) Intake valve; h) Exhaust valve

The piston (e) is fitted with a long cap (c) of a low-conductivity material; the cylinder (a) is extended to accommodate the cap. The clearance between the cap and the cylinder is rela-

tively large so that little frictional energy is dissipated in this region. The expanded gas is in contact with the low-conductivity cap, and sealing is achieved in the piston near the ambient-temperature end (d).

Reciprocating expanders with oil-lubricated cylinders and exit temperatures as low as 90 K are used in air liquefaction plants. The piston rings are usually made of an aluminum – bronze alloy, and the cylinder has a high-strength, replaceable, cast iron liner. To reduce heat transfer down the piston, the stroke-to-diameter ratio is ca. 2 : 1, and the piston is constructed of stainless steel because of this material's low thermal conductivity. Hollow piston rods are used to further reduce conduction heat transfer. Expanders with oil-lubricated cylinders are equipped with oil filters in the discharge line to remove any oil particles.

For exit gas temperatures below ca. 90 K or for systems in which the presence of oil cannot be tolerated, nonlubricated PTFE pistons, similar to those in nonlubricated compressors, are used. The cylinder also contains a replaceable liner.

The operating characteristics of a reciprocating expander engine in an air separation plant have been studied [60]. The following components of the energy dissipation were recorded (adiabatic efficiency, η_{ad}= 82 %):

Nonideal expansion	6 %
Valve losses	4 %
Clearance losses	4 %
Incomplete expansion	2 %
Heat inleak	2 %
Total losses	18 %

Although several patents were obtained for rotary expanders from 1898 to 1922, the first successful commercial application of an expansion turbine was made by Linde in the 1930 s. His turbine was an axial flow, single-stage impulse turbine; inward radial flow units were constructed later.

A significant contribution to cryogenic expander technolgy was the development of high-speed, gas-lubricated bearings [61,62], which enabled the successful construction of miniature refrigerators using rotor diameters as small as 8 mm operating at a speed up to 500 000 rpm. The following loss components have been reported for a radial flow expansion turbine (adiabatic efficiency, η_{ad}= 84.0 %) [60]:

Inlet losses	5.5 %
Blade (wheel) losses	3.0 %
Leakage	3.0 %
Disk friction	2.5 %
Exit loss	1.0 %
Heat transfer	1.0 %
Total losses	16.0 %

The compressor efficiency does not influence the liquid yield in a liquefier or the refrigeration effect in a cryocooler; however, the expander efficiency has a significant effect on both quantities. For example, for a Claude liquefier operating between 101.3 kPa at 300 K and 6.08 MPa, with nitrogen as the working fluid, the enthalpy values are as follows [52]:

h_1= 462.15 kJ/kg at 300 K and 101.3 kPa
h_2= 450.52 kJ/kg at 300 K and 6.08 MPa
h_3= 392.21 kJ/kg at 250 K and 6.08 MPa
h'_{e} = 225.77 kJ/kg at 101.3 kPa and s_3
h_{f}= 29.40 kJ/kg at 101.3 kPa and saturated liquid.

For an expander mass flow rate ratio of x = 0.60, the liquid yield for a system with a 100 % efficient expander is given by Equation (9):

$$y = \frac{(462.15 - 450.52) + (0.60)(392.21 - 225.77)}{(462.15 - 29.40)} = 0.2576$$

For the same conditions but with an expander having an adiabatic efficiency of η_{ad}= 80 %, the liquid yield is

$$y = \frac{11.63 + (0.80)(0.60)(166.44)}{432.75} = 0.2115$$

The effect of the expander efficiency on the work per unit mass liquefied is even more dramatic. For an ideal compressor and ideal expander, the work requirement per unit mass compressed is found from Equation (10):

$$-W/q_{\mathrm{m}} = [(300)(4.421 - 3.169) - 11.63] - (0.60)(166.44) = 264.11\,\mathrm{kJ/kg}$$

The work per unit mass liquefied is

$$-W/(q_{\mathrm{m}})_{\mathrm{f}} = 264.11/0.2576 = 1025.3\,\mathrm{kJ/kg}$$

On the other hand, for a Claude liquefier with an ideal compressor and an expander with an overall efficiency of η_{e}= 72 %, the work per unit mass compressed is

$$-W/q_{\mathrm{m}} = 363.97 - (0.72)(0.60)(166.44) = 292.07\,\mathrm{kJ/kg}$$

The work per unit mass liquefied is

$$-W/(q_{\mathrm{m}})_{\mathrm{f}} = 292.07/0.2115 = 1380.9\,\mathrm{kJ/kg}$$

The expander inefficiencies increase the work required to produce 1 kg of liquid by ca. 35 %. If a compressor efficiency of 70 % is included in the calculations, the work per unit mass liquefied increases to 2118 kJ/kg.

6. Low-Temperature Separation Systems

The principles of separating gas and liquid mixtures at cryogenic temperatures are the same as those used in the design of separation systems for near-ambient temperatures and above; however, some special problems arise in low-temperature separation systems. For example, a cooling source for condensers in a cryogenic system is not readily available; whereas in petroleum separation systems, cooling water or ambient air may be used.

For several mixtures, such as air and coke-oven gas, cryogenic separation techniques are the most economical methods of separating the mixture components.

Cryogenic separation methods include rectification, partial condensation or evaporation, and adsorption.

6.1. Minimum Work of Separation

The minimum work of separation occurs when the separation process is carried out reversibly and isothermally at temperature T_0 of the surroundings. The work per mole of mixture is given by Equation (19):

$$-W_{\mathrm{id}}/(q_{\mathrm{v}})_{\mathrm{m}} = \sum y_{\mathrm{i}}\left[T_0(S_1-S_2)-(H_1-H_2)\right]_{\mathrm{i}} \tag{19}$$

where y_{i}= mole fraction of component i; the units for entropy (S) and enthalpy (H) are J mol^{-1} K^{-1} and J/mol, respectively. Subscript 1 denotes conditions before separation, and subscript 2 denotes conditions after separation. For conditions under which the materials may be treated as ideal gases, the entropy and enthalpy changes may be written as follows:

$$S_1-S_2 = c_p \ln(T_1/T_2) - R\ln(p_1/p_2)$$
$$S_1-S_2 = R\ln(p_{\mathrm{m}}/p_{\mathrm{i}})$$
$$H_1-H_2 = c_p(T_1-T_2) = 0$$

For isothermal separation, $T_1 = T_2 = T_0$. The initial pressure p_1 is equal to the partial pressure p_{i} of the component in the mixture, and the final pressure p_2 is equal to the mixture pressure p_{m}. The quantity R is the gas constant. Making these substitutions into Equation (19), the following expression is obtained for the minimum work of separation:

$$-W_{\mathrm{id}}/(q_{\mathrm{v}})_{\mathrm{m}} = RT_0 \sum y_{\mathrm{i}} \ln(1/y_{\mathrm{i}})$$

where $y_{\mathrm{i}} = p_{\mathrm{i}}/p_{\mathrm{m}}$ for an ideal gas.

Separation of Air. The ideal work of separation for air (a mixture of 78.1 mol % nitrogen, 21.0 mol % oxygen, and 0.9 mol % argon) at a temperature of 300 K is

$$-W_{\mathrm{id}}/(q_{\mathrm{v}})_{\mathrm{m}} = (8.3143)(300)\cdot$$
$$[0.781\ln(1/0.781) + 0.210\ln(1/0.210) + 0.009\ln(1/0.009)]$$
$$= 1405\,\mathrm{J/mol}$$

The ideal work per mole of oxygen is

$$-W_{\mathrm{id}}/q_{\mathrm{v}}(\mathrm{O_2}) = 1405/0.210 = 6690\,\mathrm{J/mol}$$

Similarly, the ideal work per unit mass of O_2 is

$$-W_{\mathrm{id}}/q_{\mathrm{m}}(\mathrm{O_2}) = 6690/32 = 209.1\,\mathrm{J/g}$$

If the oxygen is separated from the mixture and the nitrogen and argon are not separated, the ideal work per mole mixture is

$$W_{\mathrm{id}}/q_v = (8.3143)(300)\cdot$$
$$[0.790\ln(1/0.790) + 0.210\ln(1/0.210)]$$
$$= 1282\,\mathrm{J/mol}$$

The ideal work per mole and per unit mass of O_2 separated are

$$-W_{\mathrm{id}}/q_{\mathrm{v}}(\mathrm{O_2}) = 6105\,\mathrm{J/mol}$$
$$-W_{id}/q_{\mathrm{m}}(\mathrm{O_2}) = 190.8\,\mathrm{J/g}$$

Thus, the ideal work is smaller if only one of the components is separated from the mixture.

6.2. Properties of Mixtures

The number of independent thermostatic properties required to fix the state of a mixture is given by the *Gibbs phase rule:*

$$F = C - P + 2$$

where C = number of components and P = number of phases present. For a ternary (three-component) mixture in the vapor phase, four independent properties are required to determine the state of the mixture. For example, if the mixture pressure, mixture temperature, and mole fractions of two of the components are specified, all other thermostatic properties can then be determined.

Properties of mixtures may be presented in various forms. One of the common representations for binary (two-component) mixtures is the temperature – composition diagram, as shown for the nitrogen – oxygen system (Fig. 31).

Figure 31. Temperature – composition diagram for nitrogen – oxygen mixtures

In this figure, mole fraction is plotted against mixture temperature for a fixed value of mixture pressure. The upper line in each pair of curves is called the *dew line* because this curve represents the temperature, for a given composition of the mixture, at which the vapor mixture begins to condense. The dew line corresponds to the condition of the saturated vapor in the two-phase mixture.

The lower line in each pair of curves is called the *bubble line* because this curve represents the temperature, for a given composition of the mixture, at which the liquid mixture begins to boil. The bubble line corresponds to the condition of the saturated liquid in the two-phase mixture.

The mixture properties may also be plotted as shown in Figure 32. This equilibrium diagram is important in the design of rectification columns to determine the number of "theoretical plates" required.

Figure 32. Equilibrium diagram for nitrogen – oxygen mixtures

The relationship between the mole fractions y and x in the vapor and liquid phases, respectively, may be expressed in terms of the distribution coefficient K (sometimes called the equilibrium ratio), defined for component j by [63]:

$$K_j = y_j / x_j$$

For an ideal-gas vapor phase and a perfect-solution liquid phase, the distribution coefficient is given by

$$K_j = \pi_j / p$$

where π_j = vapor pressure of component j at the mixture temperature and p = mixture pressure. For real gases and solutions, the distribution coefficients must be determined either experimentally or from thermodynamic relationships along with the equations of state for the materials. A plot of the distribution coefficients for nitrogen ($K_1 = x_1/y_1$) and for oxygen (K_2) is shown in Figure 33.

Figure 33. Distribution coefficients for nitrogen (– – –) and oxygen (–)

The behavior of mixtures can also be represented in terms of the relative volatility, α_{ij}, defined by

$$\alpha_{ij} = K_i / K_j$$

As shown in Figure 34, the relative volatility for cryogenic mixtures, such as nitrogen – oxygen, is a fairly weak function of the mixture temperature for a fixed value of the mixture pressure.

The composition of the vapor and liquid phases of binary mixtures may be determined from values of the distribution coefficients or the relative volatility. From the definition of the distribution coefficient,

$$y_1 = K_1 x_1$$
$$y_2 = K_2 x_2 = K_2 (1 - x_1)$$

For a binary mixture,

$$y_1 + y_2 = 1 = K_1 x_1 + K_2 (1 - x_1)$$

where subscript 1 refers to the lower boiling point component and subscript 2 refers to the

Figure 34. Relative volatility for nitrogen – oxygen mixtures

higher boiling point component in the mixture. Solving for the mole fraction of component 1 in the liquid phase, Equation (20) is obtained:

$$x_1 = \frac{1 - K_2}{K_1 - K_2} \tag{20}$$

The mole fraction of component 1 in the vapor phase may be determined from

$$y_1 = K_1 x_1 = \frac{K_1 (1 - K_2)}{K_1 - K_2} \tag{21}$$

Equations (20) and (21) can also be written in terms of the relative volatility α_{12}, as follows:

$$x_1 = \frac{1 - K_2}{K_2 (\alpha_{12} - 1)}$$
$$y_1 = \frac{\alpha_{12} (1 - K_2)}{\alpha_{12} - 1}$$

Another set of thermodynamic curves that are import in the design of separation systems is the enthalpy – composition diagram. Values for the enthalpy at various mixture pressures for the N_2–O_2 system are given in Table 5.

6.3. Flash Calculation

In the rectification columns used in cryogenic separation systems, the feed stream is introduced into the column by expansion through a J – T valve. Determining the condition of the feed stream after expansion through the valve is important. This solution for a two-phase mixture is called the flash calculation.

Table 5. Specific enthalpies of nitrogen – oxygen mixtures

Mole fraction	Specific enthalpies ∗, J/mol					
nitrogen	101.3 kPa		202.7 kPa		506.6 kPa	
	h_b	h_d	h_b	h_d	h_b	h_d
0.0	419	7252	764	7362	1315	7536
0.1	461	7231	807	7329	1403	7507
0.2	519	7210	860	7295	1499	7478
0.3	599	7185	923	7259	1591	7448
0.4	682	7151	996	7222	1675	7415
0.5	779	7118	1079	7184	1758	7377
0.6	879	7084	1172	7145	1851	7339
0.7	984	7042	1275	7105	1947	7298
0.8	1084	6992	1388	7063	2052	7252
0.9	1181	6933	1511	7020	2152	7201
1.0	1273	6871	1644	6976	2248	7147

$*h_b$ = specific enthalpy at the bubble point; h_d = specific enthalpy at the dew point for the mixture.

If the feed stream enters the J – T valve at a molar flow rate q_v with known properties (enthalpy h_{in} and mole fraction $x_{in,j}$), a mass balance across the J – T valve yields

$$x_{in,j} q_v = y_j q_v\,(g) + x_j q_v\,(l) = y_j\,(q_v - q_v\,(l)) + x_j q_v\,(l)$$

where $q_v(g)$ = molar flow rate of vapor from the J – T valve and $q_v(l)$ = molar flow rate of liquid from the J – T valve. Introducing the distribution coefficient, $x_j = y_j/K_j$, the mole fraction of the lower boiling point component in the vapor phase leaving the J – T valve may be determined:

$$y_j = \frac{x_{in,j}}{1 + \frac{q_v(l)}{q_v}\left(\frac{1}{K_j} - 1\right)}$$

An energy balance around the J – T valve yields the auxiliary relationship for the fraction of the outlet stream, which is in the liquid phase:

$$\frac{q_v\,(l)}{q_v} = \frac{L_g - L_{in}}{L_g - L_f} \tag{22}$$

The final governing equation for the flash calculation results from the fact that the sum of the mole fractions for the vapor phase is equal to unity:

$$\sum_j y_j = 1 = \sum_j \frac{x_{in,j}}{1 + \frac{q_v(l)}{q_v}\left(\frac{1}{K_j} - 1\right)} \tag{23}$$

The solution for the condition of the liquid and vapor phases after expansion through the J – T valve involves an *iterative technique.* First, a trial temperature for the mixture, which is between the dew point and bubble point temperatures at the exit pressure of the J – T valve, is chosen. The liquid fraction can be calculated from Equation (22) using this temperature, and the right side of Equation (23) can then be determined. If the right side is not equal to unity, as it should be, a new trial temperature is chosen; the process is repeated until Equation (23) is satisfied. When the correct temperature is found for the exit stream, then the composition of the stream may be determined from the distribution coefficients and from Equations (20) and (21). Computer-aided flash calculations have been described for multicomponent mixtures [64].

6.4. Principles of Cryogenic Rectification

The rectification process involves cascading several partial evaporations and condensations that are carried out in counterflow. A schematic of a rectification column is shown in Figure 35 (see next page).

The feed stream enters the column at a molar flow rate $(q_v)_f$, enthalpy h_{in}, and a mole fraction of the lower boiling point component x_{in}. The top product (the practically pure lower boiling point component, e.g., N_2 in the air separation column) leaves the column at a molar flow rate $(q_v)_D$, enthalpy h_D, and composition x_D. Similarly, the bottom product (the higher boiling point component, e.g., O_2 in the air separation column) leaves the column at a molar flow rate $(q_v)_B$, enthalpy h_B, and composition x_B. Heat Q_B is added to the column in the boiler (e), and heat Q_D is withdrawn from the column in the condenser (b).

Figure 35. Schematic of a rectification column
a) Dome; b) Condenser; c) Liquid-on-plate; d) Downcomer (seal); e) Boiler

The vapor in the feed stream flows up the column through the layers of liquid (c) on plates or trays. As the vapor flows through the liquid, the vapor bubbles (which are at a higher temperature than the liquid) evaporate some of the lower boiling component from the liquid into the vapor bubble. The heat transfer from the bubble results in some condensation of the higher boiling component from the vapor bubble into the liquid phase. In this manner, the vapor phase becomes more enriched in the lower boiling component as the vapor flows up the column to the condenser. Similarly, the liquid phase in the feed stream flows down the column, and the liquid is enriched in the higher boiling component.

The composition of the top and the bottom product streams depends on the number of stages or plates in the upper and lower portions of the column. The number of *theoretical plates* for the column can be determined through one of two methods, the Ponchon – Savarit method [65] or the McCabe – Thiele method [66]. The Ponchon – Savarit method is an exact method, which can be applied for all materials; however, detailed enthalpy data are required. The McCabe – Thiele method is somewhat less accurate, in general, but it requires only equilibrium concentration data and is generally adequate for cryogenic systems.

The three governing relationships for the analysis of rectification columns are the conservation of mass, the conservation of mass for one component, and the conservation of energy. Applying these principles for the upper portion of the column gives

$$(q_v)_n\,(g) = (q_v)_{n+1}\,(l) + (q_v)_D \tag{24}$$

$$(y_n)\cdot(q_v)_n\,(g) = x_{n+1}\cdot(q_v)_{n+1}\,(l) + x_D\cdot(q_v)_D \tag{25}$$

$$h_n\,(g)\cdot(q_v)_n\,(g) = h_{n+1}\,(l)\cdot(q_v)_{n+1}\,(l) + h_D\cdot(q_v)_D + Q_D \tag{26}$$

where $(q_v)_n$ (g) = molar flow rate for the vapor leaving plate n, $(q_v)_{n+1}$ (l) = molar flow rate for the liquid leaving plate $(n+1)$ and entering plate n, y_n = mole fraction of the lower boiling point component leaving the nth plate in the vapor phase, x_{n+1} = mole fraction of the lower boiling point component leaving the $(n+1)$-plate in the liquid phase, h_n (g) = enthalpy of the vapor leaving plate n, and h_{n+1}(l) = enthalpy of the liquid leaving plate $n+1$. The plates are numbered from the feed plate ($n=1$) upward. The expression for the reflux ratio of the column may be determined by combining Equations (24) – (26):

$$\frac{(q_v)_{n+1}\,(l)}{(q_v)_n\,(g)} = 1 - \frac{h_n\,(g) - h_{n+1}\,(l)}{\frac{Q_D}{(q_v)_D} + h_D - h_{n+1}\,(l)} \tag{27}$$

$$\frac{(q_v)_D}{(q_v)_n\,(g)} = 1 - \frac{(q_v)_{n+1}\,(l)}{(q_v)_n\,(g)}$$

For nitrogen – oxygen mixtures and several other simple mixtures, the molar heat of vaporization is almost independent of the composition, the reflux ratio is practically constant, and the McCabe – Thiele method may be applied. The equation for the "operating line" is found by combining Equation 27 and the conservation of mass expression for the lower boiling component:

$$y_n = \left[\frac{(q_v)_{n+1}\,(l)}{(q_v)_n\,(g)}\right] x_{n+1} + \left[\frac{(q_v)_D}{(q_v)_n\,(g)}\right] x_D \tag{28}$$

The solution for the number of theoretical plates or "equilibrium stages" required for the upper portion of the column is found by successive application of Equation 28 and the equilibrium relationship $y_n = K_j x_{n+1}$, between the feed condition and the desired condition at the top of the column. Similar expressions can be written for the lower portion of the column:

$$\frac{(q_v)_B}{(q_v)_m\,(g)} = \frac{h_m\,(g) - h_{m+1}\,(l)}{\frac{Q_B}{(q_v)_B} - h_B + h_{m+1}\,(l)}$$

$$\frac{(q_v)_{m+1}\,(l)}{(q_v)_m\,(g)} = 1 + \frac{(q_v)_B}{(q_v)_m\,(g)}$$

The operating line for the lower section of the column is

$$y_m = \left[\frac{(q_v)_{m+1}\,(l)}{(q_v)_m\,(g)}\right] x_{m+1} - \left[\frac{(q_v)_B}{(q_v)_m\,(g)}\right] x_B$$

The plates in the lower section are numbered from the boiler section ($m = 1$) upward to the feed plate.

The solution for the number of theoretical plates can be determined graphically or by a direct numerical approach, using a computer.

6.5. Linde Single-Column System

One of the simplest systems for separation of air is the Linde single-column system, shown in Figure 36. The system is used to produce either liquid oxygen or liquid nitrogen, but not both.

Figure 36. Linde single-column air-separation system
a) Compressor; b) Carbon dioxide and water removal; c) Heat exchanger; d) Boiler; e) Separation column; f) J – T valve

The air feed stream is compressed (a), water vapor and carbon dioxide are removed (b), and the air is passed through a heat exchanger (c). The cool air is further cooled in a heat exchanger (boiler, d) in the lower portion of the column (e) and then expanded through a J – T valve (f). The heat exchange in the boiler produces the upgoing vapor required in the column without using an external heat source.

The liquid formed during expansion through the J – T valve is introduced at the top of the column to provide the required liquid flow down the column. The vapor at the top of the column is passed back through the heat exchanger to provide cooling for the incoming feed stream. By use of the required number of plates in the column, nearly pure liquid or gaseous oxygen may be produced.

If the product is required as a gas, the oxygen gas is usually passed back through the heat exchanger (in this case, three-channel exchanger) to provide additional cooling for the incoming feed stream. Furthermore, the feed stream must be compressed to ca. 3 – 6 MPa, because of the additional cooling provided by the return cold oxygen stream through the heat exchanger. On the other hand, if the product is desired as a liquid, then the feed stream must be compressed to ca. 20 MPa for effective operation. The pressure within the column is usually 0.13 – 0.20 MPa.

6.6. Linde Double-Column System

If both liquid nitrogen and liquid oxygen products are required, the double-column system (Fig. 37) must be used.

The feed stream is compressed (a) and water and carbon dioxide are removed (b), as in the single-column system. The feed stream passes through a heat exchanger (c) and then through the boiler (d) of the lower column (e_1), where the feed stream is further cooled. Vapor is provided for the lower column by evaporating some of the liquid in the boiler. The feed stream is expanded through a J – T valve (f_1) and introduced in the middle of the lower column, which operates at a pressure of ca. 0.5 – 0.6 MPa [67].

A portion of the liquid in the boiler of the lower column is withdrawn, expanded through a J – T valve (f_2), and introduced into the middle of the upper column (e_2), which operates at a pressure of ca. 0.13 – 0.14 MPa. The composition of the liquid in the boiler is ca. 36 – 39 %

oxygen. At a pressure of 0.51 MPa, the boiling point of pure liquid nitrogen is 94.2 K, and the boiling point of pure liquid oxygen at 0.13 MPa is 92.7 K; therefore, the liquid oxygen in the upper column can be used to condense (g) the liquid nitrogen in the lower column without requiring external refrigeration.

Figure 37. Linde double-column air-separation system
a) Compressor; b) Carbon dioxide and water removal; c) Heat exchanger; d) Boiler; e) Separation column; f) J – T valve; g) Condenser – reboiler; h) Subcooler

A portion of the liquid nitrogen from the lower column is passed through a subcooler (h), expanded through a J – T valve (f_3), and introduced at the top of the upper column.

6.7. Heylandt System

One of the commonly used air separation systems is the Heylandt system (Fig. 38). This system uses an expander to provide a significant portion of the refrigeration needed to liquefy the air.

The air feed stream is compressed (a) to a pressure of ca. 10 MPa. Water vapor is removed in the compressor intercoolers and the aftercooler. The air stream is then compressed further to ca. 14 MPa in a final stage of compression, which is driven by the expander.

Figure 38. Heylandt air-separation system
a) Compressor; b) Heat exchanger; c) Expander; d) Separation column, e) J – T valve; f) Kettle; g) Condenser – reboiler; h) Subcooler

The air is cooled to ca. 230 K in an ammonia forecooler (precooler, b_1). About one-half of the feed stream is passed through the main heat exchanger (b_2) and the remainder of the feed stream is expanded through an expansion turbine (c) to a pressure of 0.2 MPa. The stream leaves the expander at ca. 110 K and is introduced into the middle portion of the upper column (d_1). The portion of the feed stream flowing through the main heat exchanger is cooled and expanded through a J – T valve (e_1) to a pressure of 0.7 MPa. The air is then introduced into the bottom of the lower column (d_2).

Enriched liquid air (oxygen content of 36 – 38 %) is withdrawn from the kettle (f) of the lower column, expanded through a J – T valve (e_2) to 0.2 MPa, and introduced into the middle of the upper column. To provide reflux liquid for the upper column, liquid nitrogen is withdrawn from the lower column below the condenser – reboiler (g), passed through a subcooler (h), and expanded through a J – T valve (e_3) before being introduced at the top of the upper col-

umn. Nitrogen gas from the upper column is returned through the subcooler (h), the main heat exchanger (b_2), and the precooler (b_1) to provide the necessary cooling in these units.

The product liquids are removed from the condenser – reboiler (oxygen from the upper column and nitrogen from the lower column).

6.8. Argon Separation

Atmospheric air is not simply a binary mixture of nitrogen and oxygen. Rather, the composition of dry, carbon dioxide free atmospheric air is as follows (mole fraction):

Nitrogen	0.78110
Oxygen	0.20953
Argon	0.00934
Other gases	0.00003
Neon	18.19 mg/kg
Helium	5.24 mg/kg
Krypton – xenon	1.23 mg/kg
Hydrogen	0.50 mg/kg

The predominant component, other than oxygen and nitrogen, is argon, which is present at a concentration of nearly 1 mol % [68]. This argon concentration in the air feed stream means that to obtain pure oxygen and pure nitrogen an additional column must be used to separate the argon from the other components.

Argon boils at 87.3 K and 101.3 kPa; thus, its boiling point at atmospheric pressure lies between that of nitrogen (77.4 K) and oxygen (90.2 K). If all of the argon were collected with the nitrogen product, the composition would be 98.8 mol % nitrogen and 1.2 mol % argon. On the other hand, if all of the argon were collected with the oxygen stream, the composition would be 95.7 mol % oxygen and 4.3 mol % argon. Because argon is soluble in both liquid nitrogen and liquid oxygen, the argon is generally present in both streams unless it is removed during the separation process. In addition, the equilibrium composition of the ternary mixture is significantly different from that of the binary nitrogen – oxygen mixture. This fact affects the calculation of the number of theoretical plates required for the column.

Argon may be separated in the double-column system by using a separate argon column, as shown in Figure 39.

Figure 39. Argon recovery subsystem attached to the double-column air separation column
a) Kettle; b) J – T valve; c) Separation column; d) Argon column; e) Subcooler

Argon tends to collect in the part of the upper column (c_2) where the fluid has a high oxygen concentration and a relatively low nitrogen concentration. The mixture is removed from the main air-separation column at that point and is introduced into the lower portion of the argon side column (d). The vapor flows up the column and becomes enriched in argon, which has a lower boiling point than oxygen. At the top of the argon column, refrigeration is supplied by bypassing some of the liquid from the kettle (a) of the main column through the condenser of the argon column. The vapor from the condenser is returned to the upper portion of the main column.

The liquid that collects in the bottom of the argon column is primarily liquid oxygen, which is taken back to the main column. The vapor that collects in the top of the argon column is primarily argon and nitrogen, with a small amount of oxygen.

If the argon is desired as a product, the crude material from the argon column may be purified

by two techniques: (1) catalytic combustion to remove oxygen, followed by rectification to separate the argon and nitrogen, and (2) adsorption to remove oxygen, followed by rectification for nitrogen – argon separation.

In the *catalytic combustion system*, the crude argon is mixed with an appropriate amount of hydrogen gas and passed through a catalytic combustion unit to combine the oxygen impurity with hydrogen to form water vapor. The bulk of the water vapor is subsequently removed by passing the gas through a condenser; the last traces of water are removed by subsequently passing the gas through a set of alumina driers. The excess hydrogen gas is separated from the argon stream by partial condensation in the boiler of the rectification column for argon – nitrogen separation. The final gas mixture is rectified to produce essentially pure argon liquid or gas.

In the *adsorption system*, the crude argon is first passed through a rectification column to separate the nitrogen from the mixture. The oxygen – argon liquid is removed from the boiler of the column and evaporated in a heat exchanger. The gas is passed through a set of adsorbent traps filled with synthetic zeolite or other absorbent, where the oxygen is removed. If the oxygen is desired as a liquid, then the gaseous oxygen is condensed by using some of the liquid nitrogen product from the main column as the refrigerant in an argon condenser.

6.9. Neon Separation

The heat transfer rate in the condenser –reboiler in an air separation system begins to decrease after the double-column system has been in continuous operation for a long period of time (2 – 3 d). The reason for this drop in performance is the gradual collection of a noncondensable component (mainly neon and helium) on the nitrogen side of the heat exchanger. This accumulation lowers the partial pressure of the nitrogen in the mixture to the point where it no longer condenses at the condenser temperature.

This problem is solved by periodically venting a small portion of the gas from the dome of the condenser – reboiler, if the collection of neon is not required. The vent gas contains ca. 2.1 mol % neon and 0.8 mol % helium, with traces of hydrogen.

The commercial production and distribution of neon on a large scale began in the early 1960s in response to demand, e.g., as a refrigerant and for applications in decorative neon lighting [69]. Neon can be collected by using the air-separation column shown in Figure 40.

Figure 40. Neon recovery subsystem attached to the double-column air separation column
a) Main column; b) J – T valve; c) Neon condenser – rectifier; d) Subcooler

The neon – helium portion of the dome vent gas may be separated from the nitrogen by passing the gas mixture through a condenser – rectifier (c) that is cooled by liquid nitrogen expanded through a J – T valve (b_3) from the main column. The boiling points of neon (27.1 K) and helium (4.21 K) are so much lower than that of nitrogen (77.4 K) that the liquid formed in the condenser – rectifier is practically pure nitrogen. The typical composition of the vapor from the condenser – rectifier unit is 46 mol % neon, 19 mol % helium, 33 mol % nitrogen, and 2 mol % hydrogen.

The hydrogen can be removed from the mixture by using a catalytic combustion chamber followed by a drier to remove the water vapor formed during combustion. Excess oxygen and nitrogen are then removed in an adsorption trap. The helium and neon are separated in a con-

denser cooled by a closed-cycle hydrogen refrigeration system.

6.10. Physical Adsorption

When a gas contacts a solid surface, part of the gas is taken up by the solid. The general process is called sorption. If sorption is accompanied by a chemical reaction between the gas and the solid, the process is called chemical adsorption or chemisorption. If only the weak intermolecular forces between the gas and solid are involved, the process is called physical adsorption. Physical adsorption is used frequently in cryogenic separation systems because the adsorbent material can be regenerated and reused.

Several theories have been proposed to correlate the data on physical adsorption. One of the most successful theories was proposed by BRUNAUER, EMMETT, and TELLER (the BET theory), which yields the following expression for the volume of gas adsorbed per unit mass of adsorbent [70]:

$$\frac{V}{m_{\mathrm{a}}}=\frac{\mathrm{v_m}C\,(p/p_{\mathrm{sat}})}{(1-p/p_{\mathrm{sat}})\,[1+(C-1)\,(p/p_{\mathrm{sat}})]}$$

where V = volume of gas adsorbed at STP, m_{a} = mass of adsorbent, v_{m} = volume of gas required to form a monomolecular layer over the surface of the adsorbent per unit mass of adsorbent, p = partial pressure of the gas being adsorbed, and p_{sat} = saturation pressure of the gas at the adsorbent temperature. The parameter C is a function of the net energy of adsorption and the temperature of the adsorbent.

$$C=\exp\,(\theta/T)$$

where θ = difference between the heat of adsorption of the first layer and the latent heat of the gas. For adsorption of nitrogen gas on charcoal at 77.3 K, v_{m} = 0.1815 $\mathrm{m^3/kg}$, and θ = 300 K. For adsorption of argon gas on charcoal at 77.3 K, v_{m} = 0.2156 $\mathrm{m^3/kg}$ and θ = 341 K. Physical adsorption is widely used in cryogenic systems that separate and purify gas mixtures and in systems that produce and maintain a vacuum. One of the advantages of the use of an adsorbent as a vacuum pump is that the medium in the vacuum chamber is not contaminated by the oil used in mechanical and diffusion vacuum pumps. Cryogenic adsorption has substantially extended the range of separable gas mixtures. The gas mixtures that may be easily separated by using adsorption at cryogenic temperatures include methane – helium, neon – helium, hydrogen – helium, and nitrogen – carbon dioxide.

The basic arrangement for adsorption separation of a gas mixture is shown in Figure 41. The gas stream is first cooled by passing it through a heat exchanger (a) and then through one of the adsorbent beds (b_1). The component to be removed is adsorbed in the bed, which is usually refrigerated by liquid nitrogen. During this cycle, valves (c_1), (c_3), (c_6), and (c_8) are open, and valves (c_2), (c_4), (c_5), and (c_7) are closed. While adsorbent bed (b_1) is active in adsorbing the gas to be removed, adsorbent bed (b_2) is regenerated or reactivated by warming it to ambient temperature (or to a higher temperature) and purging it

Figure 41. Adsorption separation system
a) Heat exchanger; b) Adsorbent bed; c) Control valve

with a gas. When the cold adsorbent bed (b_1) becomes saturated with the material to be removed, the valves are reversed, and the regenerated bed (b_2) begins to adsorb the gaseous impurity.

1. Principles

Vacuum is the condition of a gas whose particle number density is less than that of the atmosphere at the surface of the earth. Since the particle number density is time- and location-dependent, within certain limits, an exact upper limit of vacuum cannot be specified [1]. Corresponding to this definition, the concept *vacuum* comprises an extraordinarily broad region of conditions of gases and gas mixtures. Equipment and instruments that serve to produce, apply, and diagnose these most varied vacuums are included within the concept *vacuum technology.*

Vacuum technology is an ancillary technique; it produces the vacuum needed to manufacture a product or to allow a technical component to function. Indeed, technologies that use vacuum may often be replaced by versions without vacuum. Applications of vacuums and vacuum technology are numerous and are to be found in all fields of technology. Examples are vacuum distillation in the chemical laboratory, freeze-drying in the food industry, vacuum facilities in large basic-research projects, such as fusion research and in everyday technology, such as control by vacuum in an automotive engine or the household vacuum cleaner. Figure 1 gives an

overview of the application of vacuum technology. The abscissa scale, in powers of ten, serves to compare the particle density with that of the surrounding atmosphere.

1.1. Components

Industrial vacuum systems are built up of various components:

1) Vacuum chambers or receivers
2) Piping, pipe fittings, and flanges
3) A large variety of valves for shutoff and control
4) Pumps
5) Diagnostic instrumentation, (a) for measuring total pressure and (b) for analyzing the composition of gas mixtures
6) A multitude of ancillary equipment, (a) leak testers, (b) vacuum system leadthroughs, (c) cold traps, (d) electronic control systems

By means of symbolic figures, flow diagrams represent the interplay of all these components in a vacuum system. Figure 2 shows a small selection of these flow symbols [2].

1.2. Physical Principles

The physical principles of vacuum technology are derived from thermodynamics and the kinetic theory of gases.

1.2.1. Equations of State of Gases

According to the phenomenological theory of thermodynamics, the state variables temperature T, pressure p, volume V, and its component materials characterize a system. At sufficiently low pressure the interaction between the molecules of a gas may be neglected and the ideal gas equation describes the relationship between the state variables:

$$pV = nRT = NkT \tag{1}$$

where

n = number of mols per unit volume
R = universal gas constant, $8.314\,\mathrm{J\,mol^{-1}\,K^{-1}}$
k = Boltzmann constant, $1.3805\times10^{-23}\,\mathrm{JK^{-1}}$

$N =$ number of particles per unit volume

With increasing pressure, the gas behavior deviates increasingly from that described by Equation (1). Corrections need to be made for the volume occupied by the molecules themselves and for the difference in the forces acting within and at the periphery of the volume, which lead to the van der Waals equation of state:

$$\left(p+a/V^2\right)(V-b)=RT \tag{2}$$

where *a, b* are constants specific to individual gases.

Figure 2. Some graphical symbols of vacuum technology [2]

1.2.2. Pressure and Temperature

The atomistic foundation of the kinetic theory of gases offers a satisfactory explanation of the phenomena associated with vacuum. It views an ideal gas as a collection of dimensionless mass points that move about in disarray at all possible velocities and in all possible directions without interaction. Elastic impacts of the gas particles with the container walls produce the macroscopically registered pressure:

$$p=nm\cdot\bar{v}^2/3=\varrho\cdot\bar{v}^2/3 \tag{3}$$

$\bar{v}^2$ = mean square particle velocity
n = number density of particles
m = mass of a particle
ϱ = macroscopic gas density

Pressure has the dimensions force per unit area. In pressure measurement, several units are still used.

The SI unit, the Pascal, abbreviated Pa [3] is

$$1\,\mathrm{Pa} = 1\,\mathrm{N/m^2} \tag{4}$$

In vacuum technology, the most frequently used unit is the millibar, mbar, 1 mbar = 100 Pa. Table 1 gives a compilation of the various pressure units often used.

Comparison of Equation (3) with the ideal gas equation (Eq. 1) yields Equation (5):

$$\bar{v}^2 = 3RT/M = 3kT/m \tag{5}$$

where M = molar mass of the gas

Equation (5) links the thermodynamic temperature T with the movement of the gas particles: the mean square velocity of the particles is proportional to the temperature T and inversely proportional to the mass m of the particles.

1.2.3. Thermal Mean Velocity

The $\bar{v}^2$ in Equations (3) and (5) is calculated using the *Maxwellian velocity distribution*, which can be derived from methods of statistical physics.

The number of particles dN with a velocity between v and dv is:

$$\mathrm{d}N=Nv\cdot(m/2kT)^{1.5}\cdot \exp\left(-mv/2kT2\right)\mathrm{d}v\cdot 1/4\cdot\sqrt{\pi}2$$

The resulting mean particle velocity is

$$\bar{v}=\sqrt{8RT/M\cdot\pi}=\sqrt{8kT/m\cdot\pi} \tag{6}$$

1.2.4. Thermal Particle Interactions

The interaction of gas particles with one another is determined in the kinetic theory of gases by the gas kinetic effective molecular diameter d. The collision cross section $\sigma = \pi\, d^2$. The mean free path is defined as the average distance a particle can travel between two collisions

$$\bar{l} = 1/\sigma n \sqrt{2} = kT/\sigma p \sqrt{2} \tag{7}$$

In a directed particle beam, N of N_0 participating particles have not sustained a collision after traversing a distance $x < \bar{l}$:

$$N = N_0 \exp\left(-x/\bar{l}\right) \tag{8}$$

The particle stream density through a cross section of the surface A, i.e., the number of particles per unit time per unit area impinging on a surface may be calculated from

$$j = \bar{v} n/4 = p/\sqrt{(2mkT\pi)} \tag{9}$$

where j is a measure of the maximum possible rate of vaporization in a high vacuum system. Or, in the regime of molecular flow, j can be considered as the value of the maximum particle pumping rate through an opening. For example, for nitrogen at a pressure of 10^{-6} mbar, j is $2.9\times10^{-18}\ \mathrm{s}^{-1}\ \mathrm{m}^{-2}$.

If n_{mono} designates the number of particles covering a surface in a monolayer, then, with Equation (9), the monolayer time t_{mono} for covering an initially gas-free surface may be calculated

$$t_{\mathrm{mono}} = n_{\mathrm{mono}}/\alpha j = n_{\mathrm{mono}} \cdot \sqrt{(2mkT\pi)}/p\alpha \tag{10}$$

where the sticking coefficient α is a measure of the retention probability of impinging particles.

Figure 3 shows $\bar{l}$ for helium, hydrogen, nitrogen – air, and water vapor as well as j and t_{mono} for nitrogen at room temperature.

1.2.5. Flow Regimes, Momentum, and Heat Transfer

Vacuum presumes the creation and maintenance of *pressure gradients,* which are generated by transport mechanisms caused by gradients of physical quantities. Gradients in the gas space cause transport. Thus, a concentration gradient leads to diffusion, combined with mass transfer; a velocity gradient gives rise to momentum transfer; heat transfer results from temperature differences. While diffusion plays no critical part in pumping processes, the pumping action

Figure 3. Mean free path, surface collision rate, monolayer time
a) Helium; b) Hydrogen; c) Nitrogen/Air; d) Water; e) j (nitrogen); f) t_{mono}(nitrogen)

of a substantial class of vacuum pumps depends on momentum transfer.

Thermal conductivity is the principle behind certain pressure gauges. The actual transport mechanisms depend on the pressure regime. If d is a typical length dimension for a vacuum system, then the cases $d \gg \bar{l}$, $d \sim \bar{l}$, and $d \ll \bar{l}$ must be distinguished. The Knudsen number K is introduced for classification:

$$K = \bar{l}/d \tag{11}$$

In the case of viscous flow, $K \ll 1$. Only collisions between the gas particles determine the behavior of the gas. Wall effects may be neglected. If a velocity gradient exists in a flowing stream, then momentum transfer occurs in that direction. The faster portions of the stream are decelerated, the slower accelerated, and internal friction arises. The coefficient of the internal friction, ε, is also known as the dynamic viscosity:

$$\varepsilon = n m v \bar{l}/3 \tag{12}$$

ε is independent of pressure as long as $d \gg \bar{l}$.

Heat transfer is described by the thermal conductivity λ:

$$\lambda = n m \bar{v} \bar{l} c_{\mathrm{v}}/3 = \varepsilon c_{\mathrm{v}} \tag{13}$$

where c_{v} is the specific heat capacity of the gas at constant volume.

In the region where $K \ll 1$, both ε and λ are independent of pressure. As long as viscous flow is governed only by internal friction, the flow regime is laminar. If the convection mechanism becomes important, then the flow regime becomes turbulent. The flow regimes may be classified according to their Reynolds number [4]. Normally, turbulent flows do not arise in vacuum technology.

Through pressure reduction, the mean free path length may become greater than a typical dimension of the vacuum container, and then the region of molecular flow is attained. Equation (12), for ε, and Equation (13), for λ, lose their meaning. Now wall – particle interactions dominate. The pressure-dependent coefficient of external friction characterizes the transfer of momentum. In this regime, wall collisions impart to the gas an impulse component parallel to the wall. Also, transfer of energy is pressure-dependent and influenced additionally by the specific properties of the surfaces involved. Accordingly, the thermal conductivity in the molecular flow regime is smaller than in the region of viscous flow.

The transition region, $K \sim 1$, is designated as the region of intermediate flow. Internal and external friction have equal influence on events. Equations that embody viscous and molecular flow as limiting cases can be derived.

1.2.6. Vacuum Regimes

The Knudsen number K may be used to effect the conventional, but relatively arbitrary, classification of the vacuum regimes. Table 3 shows the assignment of values of the vacuum parameters K, $\bar{l}$, and t_{mono} to rough vacuum (RV), medium vacuum (MV), high vacuum (HV), and ultra high vacuum (UHV). Since, in UHV, the mean free path length is always much larger than the container dimensions, both K and $\bar{l}$ are less meaningful quantities. The monolayer time, t_{mono}, however, gives better information about the conditions in the vacuum vessel.

Figure 4. Vapor pressure of some materials used in vacuum technology (data from [8–10])

Rough and Medium Vacuum. The interactions within the gas characterize the regimes of rough and medium vacuum. In MV, the wall effects become stronger. Gas flows are laminar and seldom turbulent. Viscosity and thermal conductivity are independent of pressure. Sorption phenomena on the container walls may be ignored. Most vacuum processes in the chemical, food, and metallurgical industries take place in this regime.

High Vacuum. Gas – wall interactions are always a significant factor for operations in the high vacuum region. Outgassing the vessel walls contributes significantly to the gas particle balance sheet and to gas analysis, and may have major impacts on the process engineering of industrial processes. Important applications may be found in thin film technologies, e.g., manufacturing optical films, semiconductor coatings, and abrasion-resistant surfaces.

Ultra High Vacuum. In the UHV regime, the determining factors are the properties and condition of the surfaces of the vacuum equipment. Because of this, UHV equipment differs from that for the other vacuum regimes. Two basic requirements of UHV technology are accelerated degassing of surfaces by using temperatures up to 400 °C and using metal seals impervious to gases. Ultra high vacuum is required for particular coating manufacturing processes for semiconductor layers (molecular beam epitaxy [7]). Further examples of applications are analysis of the surfaces of solids, fusion research, and high-energy storage rings.

1.3. Matter under Vacuum

1.3.1. Vapor Pressure

The materials used for construction of vacuum units or the substances used within the unit, like internal parts and working fluids, may limit the attainable final pressure. The temperature-dependent pressure for equilibrium between gas and liquid or gas and solid phases can be derived by integration of the Clausius – Clapeyron equation. If a substance is present in more than one phase, then this equilibrium pressure represents the partial pressure of a substance in the system. It increases approximately exponentially with temperature (Fig. 4). For the most part, the vapor

Table 3. Vacuum ranges

Range	Pressure p, mbar	Knudsen number K	Mean free path $\bar{l}$, m	Monolayer time t_{mono}, s
Rough vacuum (RV)	$10^3 - 1$	$K \ll 1$	$10^{-7} - 10^{-4}$	$10^{-9} - 10^{-6}$
Medium vacuum (MV)	$1 - 10^{-3}$	$K \approx 1$	$10^{-4} - 10^{-1}$	$10^{-6} - 10^{-3}$
High vacuum (HV)	$10^{-3} - 10^{-7}$	$K \gg 1$	$\bar{l} > 10^{-1}$	$10^{-3} - 10$
Ultra high vacuum (UHV)	$<10^{-7}$			>10

pressures of the working fluids and sealing materials within the pumps limit the ultimate vacuum. Thus, water-filled liquid ring pumps achieve final pressures down to 15 mbar. Special pump oils with low vapor pressures make ultimate vacuums $<10^{-9}$ mbar possible with UHV pumps. Diligent attention must be directed at avoiding materials such as brass (zinc) and cadmium, which can contaminate high vacuum units at elevated temperatures.

1.3.2. Sorption, Gettering, Permeation

Van der Waals forces (physical adsorption) or chemical bonds (chemisorption) can bind gas particles to condensed matter. Deposition on the surface is called adsorption. If the gas penetrates into the body of the material, then the appropriate term is absorption. Desorption is the reversal of gas deposition. As the pressure is decreased desorption from the surfaces of vacuum equipment plays an increasing role in vacuum phenomena. If chemical processes (for example, reactive physical vapor deposition of thin coatings) take place in the vacuum gas space, these may be disturbed by desorbed gas, even at 10^{-3} mbar. The desorption also limits the attainable ultimate vacuum in the UHV region. The participating components distribute themselves according to the equilibrium between desorption and gas deposition resulting in a degree of surface coverage that depends on gas pressure. At constant temperature, the coverage can be characterized by adsorption isotherms. Through adsorption, substances with a vast internal surface, such as zeolites (molecular sieves [11]) or activated carbon can bond substantial amounts of gas and consequently pump gas. In addition to the surface adsorbed gases, the gases absorbed in the materials of the system, and the volatile constituents of the wall material itself, also contribute to gas emission into the vacuum. The gas emission is highly material-dependent and is affected by the pretreatment of the system, by the temperature, and by the duration of pumping. Table 4 lists typical desorption rates [12–14]. Figure 5 plots the desorption rate versus the pumping time. For metals, the outgassing rate is inversely proportional to the pumping time. As a rough classification, metals, glasses, and ceramics have gas emission rates $\leq 10^{-8}$ mbar m/s after a few hours. They are thus suitable for UHV. For polytetrafluoroethylene (PTFE), Viton, and a few other plastics, the gas emission is ca. 10^{-7} mbar m/s, and these materials can be used in high vaccum applications. Due to their high gas-emission rates, silicone rubber, butyl rubber, and epoxy resins have restricted use under high vacuum.

Table 4. Desorption rate of some materials at room temperature after 10 h pumping time

Material	Desorption rate, 10^{-10} mbar L s^{-1} cm^{-2}	Reference
PMMA (unfilled)	240 – 440	[12]
PMMA (filled)	770 – 4700	[12]
Epoxy (unfilled)	350 – 700	[12]
Epoxy (filled)	280 – 1000	[12]
Viton	2100	[14]

6063 aluminum	2	[13]
304 stainless steel	2	[15]
Alumina, dense	0.01	[14]

A further portion of the gas flow into the vacuum container comes about through permeation, i.e., by the flow of gas from the surrounding atmosphere through the seals and walls of the vacuum apparatus. The rate of diffusion in solids determines the rate of permeation. Unlike the rates of outgassing, permeation rates are independent of the duration of pumping. They depend ex-

ponentially on the temperature. Thus, they may limit the temperature at which a vacuum system can be degassed. Figure 6 shows the gas permeability for VITON, an elastomer in common use as a sealing material in vacuum applications. Table 5 lists some numerical values for permeability at room temperature for typical construction materials.

Table 5. Permeability of some materials at room temperature. Pressure difference 1 bar, Sample thickness 1 mm.

Figure 6. Permeation of various gases through VITON [17] a) Helium; b) Hydrogen; c) Argon; d) Nitrogen pressure difference 1 bar, sample thickness 1 mm

An adsorbent to which gas binds chemically can be termed a *getter*. In contrast to reversible physical adsorption (bond energies ≤ 10 kJ/mol), chemisorption is the result of bond energies > 100 kJ/mol and, in general, is irreversible. There is a distinction between sorption getters and vaporization getters. *Sorption getters* in the form of powders, sintered solids, or foil can bind gases within the body of the material. Getters in this group are titanium, thorium, zirconium and zirconium – aluminum alloys [18]. Subjecting a *vaporization getter* to evaporation produces a fresh, chemically active surface. The best vaporization getters are titanium, thorium, zirconium [19], barium, calcium, and strontium [18]. Getters can only bond chemically reactive gases, chiefly O_2, N_2, CO_2, and H_2, not the noble gases. Figure 7 shows examples of the effectiveness of various getters for hydrogen.

2. Evacuation

2.1. Characteristic Quantities

In order to produce a vacuum, gases must be transported through vessels, openings, piping, and pumping equipment. Some concepts, defined in detail, for example, in [16], serve to describe these operations. The throughput, $q_p\, v$, through the area A is a constant for the entire pump device:

$$q_{\mathrm{p}}\, v = p \cdot \Delta V / \Delta t = p\, A\, \bar{u} = \text{ constant} \tag{14}$$

where $\bar{u}$ = mean flow velocity over the cross section A

Suction capacity is the term used for the throughput for pumps. If p_1 is the pressure on the suction side of the pump, then one defines the pumping speed (ISO: volume flow rate) as:

$$S = q_{\mathrm{p}}\, \mathrm{v} / p_1 \tag{15}$$

Equations (9), (14), and (15) may be combined to give the theoretical pumping speed, the pumping rate required to remove all particles impinging on the surface A

$$S_{\mathrm{th}} = \mathrm{v} \cdot A / 4 \tag{16}$$

If p_2 designates the pump outlet pressure, then the pump compression ratio is:

$$\tau = p_2 / p_1 \tag{17}$$

The resistance to flow is:

$$R = (p_1 - p_2) / q_{\mathrm{p}}\, \mathrm{v} \tag{18}$$

And the flow conductance is:

$$C = 1/R = q_{\mathrm{p}}\, \mathrm{v} / (p_1 - p_2) \tag{19}$$

R and C are characteristic quantities for describing openings and piping.

If the pumping speed S is limited by a flow resistance with the conductance C caused by valves, baffles, or other component parts, as is always the case in a real layout, then one obtains an effective pumping speed by combining Equations (14), (15), and (19):

$$S_{\mathrm{eff}} = S \cdot C / (S + C) \tag{20}$$

Then the pump-down time t_{p} for a volume V necessary to reach a pressure p starting out from pressure p_0, may be determined using S_{eff}:

$$t_{\mathrm{p}} = V \cdot \ln (p_0 / p) / S_{\mathrm{eff}} \tag{21}$$

Assumptions for application of Equation (21) are negligible leak and outgassing rates and a constant S_{eff} in the pressure range under consideration. Therefore, in general, Equation (21) has absolute validity only in the medium vacuum region.

If several component elements are connected in series, their flow resistances are additive; if parallel, the conductances are additive.

Flow resistances and conductances depend on the geometry of the component parts and on the flow regime. For simple geometries, derived formulas can be produced, for example, see [16]. The ultimate vacuum is that produced after a long period of pumping by a continuously operating pump. The back pressure stability determines the maximum allowable pressure on the discharge side of the pump. For pumps with high compression ratio τ, the water vapor compatibility is also important. This decides the highest possible water vapor partial pressure in the intake gas.

2.2. Classification of Vacuum Pumps

To master the large range of particle densities embraced by the concept *vacuum* requires the application of extremely varied principles. The actual mechanism of the positive displacement pumps can be derived from the ideal gas law equation (Eq. (1)). The cavity in the pump whose volume varies periodically forces the gas from an inlet at pressure p_1 through the pump to the outlet at p_2. According to Equations (16) and (17), the pumping speed of a positive displacement pump operating periodically is independent of pressure: it is the product of the displacement volume V_1 and the frequency of filling the displacement volume ν_1:

S (for positive displacement pumps) = $V_1 \cdot \nu_1$

Yet, due to sealing losses (leaks) and the partial pressure of the pump working fluid, pressuredependence does arise at low pressures; S falls very quickly to the unusable low values shown by Curves a and b in Figure 8. Provided

Figure 8. Volume flow rates of pumping units

that isothermal conditions prevail and that Equation (1) is valid, the pump power requirement P may be calculated.

$$P = p_1 \cdot \ln\,(p_1/p_2)$$

Accordingly, for p_2 equal to atmospheric pressure, P goes through a maximum at p_1 equal to 390 mbar (Fig. 9). This power requirement curve must be considered in designing pumps for the anticipated inlet pressures and in providing for cooling. Positive displacement vacuum pumps are used almost exclusively in the rough and medium vacuum ranges, very often as the high pressure pumping stage, or forepump, in combination with high vacuum pumps.

For kinetic vacuum pumps, the fundamental basis for the pumping effect is momentum transfer. This is described by Equation (12) in the region of viscous flow and characterized in molecular flow by the pressure dependence of external friction. The class of working fluid vacuum pumps uses the gas – gas interchange effect; the molecular drag vacuum pumps use the gas – wall interchange effect. At low pressures, the pumping speed is limited by backflow of the working fluid or of the pumped gases. At high pressures, the pumping mechanism breaks down because the mean free path length becomes too small. Curves c and d in Figure 8 are examples of the trend of the pumping speed of kinetic vacuum pumps. Depending on the type of momentum transfer and on the nature of the working fluid, kinetic vacuum pumps cover all vacuum regimes from rough to ultra high vacuum.

Figure 9. Pump power P/theoretical volume flow rate $S_{\mathrm{theor.}}$ vs. inlet pressure of positive displacement vacuum pumps

Positive displacement pumps, working fluid pumps, and molecular drag vacuum pumps move gases through the pumps by compression from the inlet to the outlet opening. Entrapment vacuum pumps accumulate the pumped gas in

some form within the body of the pump itself. They use the gas bonding action of getter materials, including the use of electrical fields. Curve e of Figure 8 shows that pumping speed remains almost constant even at low pressures. Or, gas bonding takes place by cryocondensation and cryoadsorption at low temperatures. The pumping speed of these pumps achieves almost the theoretical value specified by Equation (16). The most prominent application for entrapment pumps is for ultra high vacuum, although modern cryopumps are increasingly applied in the medium vacuum range. While Figure 8 shows the pumping speed trend for a typical representative of the various pump types, Figure 10 shows the throughput of vacuum pumps, that is, the delivered gas volume per unit time referred to atmospheric pressure. Figure 11 gives an overview of the principal vacuum application ranges for various types of pumps.

2.3. Technology of Vacuum Pumps

2.3.1. Displacement Pumps

The reciprocating piston and membrane pumps are oscillating positive displacement pumps. These push gas through the pump by back and forth movement of the pistons or membranes. Membrane pumps are used for light services in the laboratory. Reciprocating piston units still find application in the chemical industry as pumps for rough vacuum. In comparison, rotary positive displacement pumps, which are treated in the following paragraphs, have great importance. In these, rotating internal parts periodically produce the displacement volume.

2.3.1.1. Liquid and Gas Ring Vacuum Pumps

The liquid ring vaccum pump is a simply constructed rotary positive displacement pump. A rotor provided with buckets is mounted eccentrically within a stationary housing filled with a working fluid. Its rotational motion produces a rotating liquid ring within the housing (Fig. 12 A). The liquid ring creates a sickle-shaped displacement volume, which is partitioned by the buckets into separate cells. The eccentricity of the rotor within the housing causes oscillation of the liquid ring within the cells. In turn, these oscillations result in compression of the gas to atmospheric pressure through correspondingly-shaped suction and discharge openings in the front and back walls of the housing. Adding working fluid through an additional

Figure 11. Vacuum ranges for pumping units [28]
Range of operation with special design or with particular operating data.

opening compensates for losses caused by combination with the gas exhaust.

With water as the working fluid (the usual case), these pumps can achieve an ultimate vacuum <30 mbar depending on the water temperature. If the gas being pumped contains water vapor, then the liquid ring pump acts simultaneously as a condenser, and its pumping speed rises above the value for positive displacement pumps. The pumps can handle up to 5 % of the volume resulting from the pumping speed in the form of dust or liquid droplets without difficulty [29]. The pumping operation effectively cools hot process gases. The simple construction permits the use of corrosion-resistant materials, for

example, ceramics. It also leads to high reliability and low maintenance cost.

A very similar pump in physical design and range of application is the gas ring vacuum pump. It consists of a turbine wheel provided with a multitude of buckets which accelerate the gas from the side, outwards into a toroidal-shaped channel leading around the pump. In this manner, a compression takes place to atmospheric pressure, or beyond. The gas ring pump, according to the physical principle involved, does not belong to the positive displacement pump group, but to the kinetic vacuum pumps treated later.

2.3.1.2. Sliding Vane Rotary, Rotary Plunger, Rotary Piston Pumps

Sliding vane rotary, rotary plunger, and rotary piston pumps are for the most part oil-sealed rotary positive displacement pumps that work with a rotating piston principle. The sliding vane vacuum pump (Fig. 12 B) has a rotor placed eccentrically within a stator. Movable sliding vanes (generally two) are fastened in a slot in the rotor. Forced outward by springs, these vanes slide on the stator inner wall, thereby producing reciprocating displacement volumes that act to compress the gas. The gas discharges to atmospheric pressure through an exhaust valve. Sliding vane vacuum pumps may be built with one pump stage or with two stages connected in series. The achievable ultimate pressure is ca. 0.01 mbar with a single stage and < 0.001 mbar with a two-stage series design. The achievable ultimate pressure depends on the partial pressure of the pump seal oil and the quantity of gas dissolved therein. The pumping speed of commercially available units ranges from 0.2 to $> 500\,m^3/h$.

The high compression ratio of the sliding vane pump may lead to condensation of the vapor contained in the inlet gas within the pump. As a result, pump capacity no longer suffices and the incompressible liquid may cause serious damage or corrosion. A remedy, up to a certain vapor concentration, is gas ballasting: supplementary air or inert gas is admitted into the pump. This reduces the partial pressure of the vapor in the gas at the discharge pressure to the point at which no condensation takes place. A measure of the allowable vapor in the inlet gas is the water vapor tolerance. For jacketed pumps having optimal construction and uniform heating of the pump internal volume, the allowable water vapor partial pressure lies at 70 mbar in the inlet gas.

Sliding vane rotary pumps are ideally suited for clean and dry vacuum operations and for small to medium inlet capacities in the range of atmospheric pressure down to medium vacuum. Contaminated oil fog in exhaust gas can be removed by separation. The amount of waste oil formed is usually small. If large amounts of condensable vapors or corrosive gases and dusts are pumped out with the gas, then a separator must

be installed. The pumping oil must then be purified in an external filtration loop. The residual gas from a sliding vane pump contains traces of oil vapors and cracked products from the pump seal oil.

The chief application for sliding vane rotary pumps in a vacuum system is as the high-pressure pumping stage for operation in the medium vacuum range. Various special designs are commercially available:

1) To overcome corrosion problems, continuous fresh oil feed may be used instead of a permanent oil charge
2) Tightly sealed pumps suitable for holding helium are available for the nuclear power industry
3) Dry-running sliding vane pumps avoid the possibility of oil vapors entering the vacuum vessel from the pump

Related to the sliding vane are the rotary plunger and the piston rotary vacuum pumps. In the former, a piston rotates eccentrically in a stator housing. A stationary sliding seal plate coupled with the piston serves to disengage the pump inlet from the discharge opening, allowing gas compression by the rotor. In the latter, the piston has a trochoidal cross section whose center of gravity produces a circular path as the pump moves. Both types of pump, being oil-sealed, have similar features to sliding vane pumps. They are applied as rugged rough-vacuum pumps for industrial processes, mostly with pumping speeds $>500\,m^3/h$.

2.3.1.3. Rotary Lobe Vacuum Pumps

In rotary lobe vacuum pumps, or *Roots pumps*, the pump housing contains two figure-eight-shaped rotors. These revolve counter to one another, turning with little clearance between them (Fig. 13 A). The compression ratio is always less than 100, therefore they can also pump gases with high concentrations of condensable vapors. Apart from rate of rotation and displacement volume, gas backflow through the clearance between rotors and walls, and gas left in the clearance volume also determine the pumping speed. Because of gas flow losses, the pumping speed depends on the type of gas (Eqs. (13) and (16)). The power requirement of a Roots pump is proportional to the pressure difference between discharge and suction pressure. Therefore, without incurring excessive temperatures, they can only be operated up to a maximum pressure difference of the order of 100 mbar. The necessary forepump must be chosen to assure the specified quantity of gas is pumped while maintaining the specified working vacuum. The pump operation against atmospheric pressure is also possible with a gas-cooled rotary lobe pump: cooled gas at atmospheric pressure, from an aftercooler, is mixed with the suction inlet gas between the suction and discharge pump stages.

Figure 13. Medium and high vacuum pumps
A) Roots vacuum pump; B) Working fluid jet vacuum pump; C) Diffusion pump; D) Turbomolecular pump

Rotary lobe vacuum pumps in combination with suitable forepumps, correctly designed, achieve ultimate vacuums under 10^{-4} mbar. They are manufactured with pumping speeds from 150 to $>25\,000\,m^3/h$. They are applied universally in the rough and medium vacuum regimes, either as the low pressure stage in series with a pump discharging at atmospheric pressure or as an intermediate pump stage, for example, after a high vacuum diffusion pump. Since it

has no rubbing parts, the Roots pump is rugged and wear-resistant. Lubricating the bearings and drive requires oil, but, because of the low consumption, expensive oils with low vapor pressure can be used. A Roots pump can be driven by an electric motor enclosed within the pump housing, avoiding an opening for the shaft and the seal that goes with it. Thus it can be made completely vacuum-tight, minimizing the potential for escape into the surrounding air of, for example, radioactive or toxic gases.

2.3.1.4. Pump Oils for Rough and Medium Vacuum Pumps

Apart from some dry sealed special constructions, rotary vacuum pumps use oil for lubrication and sealing. Besides lubricity, the oils must exhibit the following characteristics:

1) Low vapor pressure, $\leq 10^{-3}$ mbar
2) Sufficient chemical inertness at the operating temperature, especially oxidation resistance
3) Low solubility for the gases being pumped

Apart from narrow mineral oil fractions, saturated paraffins, and mineral oils containing antioxidants, synthetic silicone oils, ethers, esters, and fluorocarbon compounds find use, especially under more severe chemical conditions [5]. The vapor pressure of commercial forepump oils at room temperature is less than 10^{-4} mbar, and the average molecular weight is mostly greater than 400. For fluorocarbon compounds, molecular weight is greater than 1000; the flash point is higher than 220 °C, or the compounds are not flammable. Synthetic pump oils cost up to one hundred times as much as simple mineral oils. Under certain circumstances, however, reprocessing expensive used pump oils can bring substantial cost savings [30].

2.3.2. Kinetic Vacuum Pumps

Kinetic vacuum pumps are gas-transfer pumps whose pumping action relies on the transfer of momentum between the gas and a liquid working fluid, or between gas streams having different velocities (Eq. (14)) or between the gas and a solid surface in some form (Eq. (16)). As a consequence, one differentiates between working fluid and mechanically acting kinetic vacuum pumps.

2.3.2.1. Working Fluid Jet Vacuum Pumps

Pumps operated with working fluids in the regions of viscous and intermediate flow are called working fluid jet vacuum pumps. The working fluid flows through a nozzle into a mixing chamber. The reduced static pressure (Bernoulli equation) forces gas from the suction into the mixing chamber. The working fluid entrains the suction gas into a diverging nozzle where, together, they are compressed and discharged (Fig. 13 B).

The best known example is the water jet pump. Its poor ultimate vacuum, ca. 20 mbar, its low pumping speed, mostly <1 m^3/h, and its high water consumption limits its use to simple laboratory applications. Gas jet or vapor jet vacuum pumps use gas or vapor working fluids, the latter usually steam. After passage through the diverging nozzle, the inlet gas mixed with the working fluid vapor passes into a condenser, which serves to separate working fluid and pumped gas. A forepump transfers the separated gas to the next, higher pressure stage. If desired, the condensed working fluid may be returned to the pumping operation through a closed recycle loop.

Vapor jet vacuum pumps have a maximum compression ratio of ca. 20. Therefore, to achieve an ultimate vacuum <1 mbar requires connecting several in series. To avoid pumping the working fluid vapor, and possibly suction inlet vapors, through all the pump stages, condensers are usually installed between the pump stages. The most economical operation requires careful consideration of the coordination of the condensers, the cooling temperature in the condensers, the pumping speeds, and the working fluid vapor pressures. Vapor jet vacuum pumps are commercially available in sizes from small units suitable for the laboratory to large installations with pumping speeds $>10^6$ m^3/h at 0.5 mbar inlet pressure.

Especially when equipped with intercondensers, operation is completely unaffected by high levels of dirt in the inlet suction gas. The low investment cost for the pump offsets the disadvantage of high working fluid consumption and cost. Due to the simple design, almost any material can be used to construct the pump. Therefore, vapor jet pumps can also be used in the chemical process industries to pump the most aggressive media.

2.3.2.2. Diffusion Pumps

Diffusion pumps [31] (Fig. 13 C) consist of three to four stages of Laval nozzles arranged around a central standpipe within an outer pipe (air-cooled in small, water-cooled in large units). The working fluid in a reservoir is heated, vaporized, and flows through the standpipe and issues from the nozzles at supersonic velocity. The gases being pumped diffuse into the vapor jets which are directed downward and against the outer pipe and thus, through momentum transfer, a downward velocity component is created. The working fluid condenses on the outer wall and flows back into its reservoir. Each stage develops a compression ratio between 100 and 1000. Compressed gases at pressure p_2 flow through the pump discharge nozzle into the suction nozzle of the forepump.

The working fluids are a wide variety of high vacuum oils, today only rarely mercury. Pumping speed, oil vapor backflow, and forepumping stability determine operational behavior. Velocity components of the working vapor molecules that are directed away from the jet, especially near the nozzles, result in oil vapor backflow into the chamber being pumped out. Also, the gas molecules being pumped may again separate from the working vapor jet in the direction of the receiver. That is why the actual pumping speed for air amounts to only 60 % and for hydrogen only 30 % [31] of the theoretical values given by Equation (16).

To achieve the ultimate vacuum of $<10^{-9}$ mbar, special condensation devices serve to avoid oil vapor backflow. Cold caps above the uppermost row of nozzles and baffles in the suction opening are appropriately-shaped water-cooled plates on which the oil vapor almost completely condenses. Further reduction of oil vapors results with liquid-nitrogen-filled cold traps. These devices, as well as the necessary high vacuum valve on the suction side, reduce the pumping speed of diffusion pumps by about 10 – 50 %.

Oil diffusion pumps are commercially available with pump speeds from 150 to 180 000 m^3/h at 10^{-5} mbar suction pressure. In the medium vacuum field, ejector diffusion pumps, which combine a diffusion pump with a vapor-jet pump stage, have even greater pump speeds. The forevacuum stability provides information about the maximum allowable pressure p_2 on the forepump suction side. For the usual oil diffusion pumps, p_2(max) is ca. 0.5 mbar. Diffusion pumps are typically applied in the high vacuum field. They are less suitable for the UHV region because of oil vapor backflow. In the medium vacuum regime, they are limited by low pumping speed. Since they have no moving parts, they are extremely reliable in operation. With suitable working fluids, they can also pump chemically aggressive gases without problems. By itself, dust, which would cause damage to mechanical pumps, does not adversely affect the functional effectiveness. Nevertheless, the importance of oil diffusion pumps has declined in favor of the much more expensive, but also much more effective turbomolecular and cryopumps. The latter may be applied over a broader range of vacuum and do not show the disadvantages of oil backflow and low back pressure stability.

2.3.2.3. Jet Pumps–Working Fluids [5]

The lubricating properties of the working fluid are unimportant for vapor jet and diffusion pumps. The following points require consideration:

1) The working fluids should have a low vapor pressure
2) The working fluids should not be subject to thermal decomposition at the operating temperatures, ca. 250 °C
3) The working fluids must vaporize easily
4) The gases being pumped should have low solubility in the fluid
5) The working fluids should be chemically inert to the gases being pumped

Since no liquid in itself exhibits all of these properties, the correct choice among the possible working fluids depends on the specific application. Table 6 lists some typical working fluids and their characteristics. Mineral oils are inexpensive; however, they do not have a low vapor pressure, are easily oxidized by oxygen, and are subjected to thermal decomposition. The silicone oils possess the lowest vapor pressure and are very resistant to oxidation. Various ethers have low vapor pressure, and they are resistant to corrosive gases. Fluorocarbon compounds are the most stable.

Table 6. Characteristics of some typical diffusion-pump fluids

Trade name	Compound	$\bar{M}_r$	p (25 °C), mbar	p_{end}, mbar	Reference
Apiezon C	mineral oil	479	1×10^{-8}	1.3×10^{-7}	[32]
DC 705	trisiloxane	546	4×10^{-10}	6×10^{-10}	[33]
Diffilen ultra	mineral oil	530	3.5×10^{-9}	1.3×10^{-9}	[33]
Fomblin 25/9	perfluorpolyether	3300	7×10^{-9}	$<2.5\times10^{-8}$	[35]
Kryotox 1625	perfluorpolyether	3700	9×10^{-10}		[36]
Santovac 5	pentaphenylether	447	1×10^{-10}	$<1\times10^{-8}$	[34]
Ultralen	polyphenylether	454	1.8×10^{-9}		[33]

2.3.2.4. Drag Vacuum Pumps–Turbomolecular Pump

Mechanical kinetic vacuum pumps include the gaseous ring vacuum pumps previously discussed, which are applied in the field of viscous flow, and liquid ring pumps and turbomolecular pumps (Fig. 13 D), which are used for pumping in the molecular flow region. Turbomolecular pumps are multistage units, each stage consisting of a set of rotor turbine blades and a set of stator blades stationed between each rotor wheel. Each blade represents an elemental unit that acts as a pump through transfer of momentum between the moving and the inwardly diffusing gas [37]. Hence, the turbomolecular pump represents an assembly of individual pump stages arranged in series and an assembly of many elemental pumps connected in parallel.

The pump speed is independent of the nature of the gas in the molecular flow regime. It does depend on the blade geometry and the circumferential velocity of the rotor. To achieve rotor velocities in the range of molecular kinetic velocities requires using rotational speeds up to 90 000 rpm. The efficiency decreases with increasing suction pressure and approach of the mean free path length to the pump dimensions. Because of the clearances between stator and rotor, limited by operational and manufacturing technical considerations to up to 1 mm, gas backflow in a pump stage is substantial and dependent on the nature of the gas.

The compression ratio, τ, is proportional to the square root of the molecular mass (Fig. 14). While τ is ca. 4×10^3 for hydrogen, the value for a gas with M_r 86 is 10^{15}. Therefore the residual gas above the pump consists essentially of hydrogen and oil vapors are not detected. With suitable forepumps, final pressures in the range of 10^{-11} mbar are possible.

Figure 14. Compression curves of a turbomolecular pump [38]

Turbomolecular pumps can be started up at atmospheric pressure and also tolerate air break-

ins at full speed. Thus, they also do not require a high vacuum suction valve and can be flanged directly to the vacuum receiver.

Commercially available types of turbomolecular pumps have pump speeds between 100 and 32 000 m^3/h in the high vacuum region. They are all-purpose high vacuum and UHV pumps for producing hydrocarbon-free vacua. Their response to big upsets in gas flow is less sensitive than that for diffusion pumps. With special design, they are also suitable for pumping corrosive or radioactive gases. They are largely maintenance-free. Problems may arise in UHV applications due to the molecular-mass-dependent compression. Due to the high rotational speeds and the restricted mechanical tolerances, inflow of foreign particles may destroy the pump. There are two design configurations: double flow pumps with two pump rotor-stator sets horizontally supported symmetrical to the suction nozzles and single flow pumps with the pump shaft oriented in the direction of the suction nozzle. The single flow pump has been gaining increasing acceptance due to its lower space requirement and the possibility, at least for smaller pumps, of assembly at any site.

2.3.3. Entrapment Vacuum Pumps

In contrast to gas transfer pumps, the pumping action of the gas-bonding vacuum pumps is based on sorption and condensation of the gases being pumped within the body of the pumps. Thus, it is necessary to operate gas-bonding pumps cyclically. A regeneration operation, which restores the full gas-bonding capacity, follows each onstream pumping cycle.

2.3.3.1. Sorption Vacuum Pumps

Sorption vacuum pumps use the most varied potential physical and chemical sorption operations. Adsorption vacuum pumps consist of a closed, stainless steel vessel filled with a Zeolite. It is equipped not only for heating, but also for cooling with liquid nitrogen. By means of physical adsorption, the cooled sorbent easily condenses most gases, except neon and helium, and some hydrogen in the region from atmospheric pressure to ca. 0.01 mbar. Heating to 200 °C regenerates the pump. As forepumps, adsorption pumps produce completely hydrocarbon-free vacuums for UHV experiments.

Sorption getters are materials that bond gases into the solid state. They are used in sealed component parts like cathode ray tubes or vacuum switches to pump desorbed gases or gases flowing in through permeation. In addition, very special applications in mass spectrometers, space flight missions, in storage and accelerator rings, and for gas purification are well-known (NEG pumps, non-evaporable getters [16], [39]).

The use of the vaporizing getter, titanium, is more widespread. In the titanium sublimation pump, titanium from a hot coil or a sphere heated from within is vaporized, continuously or under pressure control, onto the surrounding surfaces. The freshly deposited film very effectively bonds all gases other than the noble gases. The pump speed depends on the nature of the gas, the pump configuration, the cooling of the pump surfaces, and the titanium evaporation rate. With liquid nitrogen cooling, it can approach the theoretical value for hydrogen and nitrogen (Eq. 16). Titanium sublimation pumps are supplemental auxiliary pumps of high pumping speed for the pressure range from 0.01 to $<10^{-8}$ mbar. They are used exclusively in UHV systems.

2.3.3.2. Getter Ion Pumps

Several getter ion pump designs are available. Units using the diode principle consist of flat titanium cathodes fastened on both sides of the opening of a tubular anode. Others using the triode principle combine flat anodes with cathodes in the form of grids behind which are collector electrodes at the anode potential. In both, a gas discharge is ignited between anodes and cathodes, intensified by magnetic fields from powerful permanent magnets and maintained even at the lowest pressures. The ions of the gas discharge atomize the titanium of the cathodes which, on the one hand, reacts with the gases forming compounds (getter effect), and on the other hand, also entrains gas particles mechanically (pumping the noble gases). Especially in the case of diode pumps, the overall pumping characteristic is dependent on the previous history; above all, entrained argon may again be-

come freed in a subsequent pumping operation (memory effect).

The getter ion pump is a UHV pump for ultimate vacuums in the range 10^{-11} mbar. Its pump speed depends on the pressure and on the nature of the gas. For air, single units are available with capacities of the order of 2000 m^3/h at 10^{-6} mbar. Frequently, titanium getter ion pumps and titanium sublimation pumps are combined in one unit, the so-called UHV booster.

2.3.3.3. Condensation Pumps

Freezing out vapors and gases being pumped onto sufficiently cooled surfaces is the basis for condensation pumps. The pump speed depends not only on the gas properties, the pump surfaces, and their temperature, but also on the degree of coverage of the surface by the gas and the effectiveness of screening against thermal radiation from the pump surroundings. When loaded with condensed gas, the pump is regenerated by warming.

Condensation pumps operating with cooling media temperatures above 120 K are called vapor condensers [27]. Piping, plates, and fins for the cooling medium are designed for a specific system to remove large quantities of water and solvent vapors from the process atmosphere. Vapor condensers are used in industrial processes in the range 0.2 – 0.01 mbar [40]. The pump speed for the case of water on a clean cooled surface at temperatures below −50 °C is close to theoretical. However, pump speed decreases with increasing loading of the cooling surface due to the poor thermal conductivity of the condensate. The value of the ice capacity characterizes the vapor condenser. The ice capacity designates the mass of ice which can be frozen out per day with a certain coating thickness on the whole vapor condenser. The pump operation is meant to be effective at the selected coating thickness.

Condensation pumps with temperatures <120 K are called cryopumps [41]. These are able to pump gases that are noncondensable at room temperature and if activated carbon is present even hydrogen, neon, and helium. The gas-bonding occurs by cryocondensation when the gas, at operating temperature and pressure, can be transferred into the solid or liquid phase; by cryotrapping when noncondensable gases are stored in the growing layer of condensate; and by adsorption on surfaces coated with adsorbent, usually activated carbon. In general, cryopumps can be operated so that the pump speed is equal to the maximum possible pump speed (11.6 L/s for air, 14.5 L/s for hydrogen, Eq. 16). For pump openings of equal size, cryopumps have the highest pumping speed of all vacuum pumps. They can achieve final pressures $<10^{-11}$ mbar.

The cooling medium in most cryopumps is helium. Cryopumps are differentiated according to the style of arrangement of cooling devices into bath cryopumps, vaporizer cryopumps, and refrigerator cryopumps. Bath cryopumps are vessels filled with boiling liquid helium. Therefore, the cooling medium temperature is 4.2 K at atmospheric pressure or even 2.5 K at reduced pressure. The cooling surfaces must be protected from thermal radiation by liquid-nitrogen-cooled shields. The arrangement of the pump is fixed by the need for charging with liquid helium.

In vaporizer cryopumps, vaporizing helium is pumped from cooling coils. Varying the flow rate of helium controls the cooling temperature. The pump manages without liquid nitrogen since the helium pumped out serves to cool the thermal-radiation shields. There is no size limitation for vaporizing cryopumps.

Refrigerator cryopumps are usually two-stage vaporizer cryopumps with a helium refrigerator creating a closed helium recycle loop. The second stage cools the "cold head" operating between 10 and 20 K. The cold head is partially covered with activated carbon. The first stage cools the radiation shield around the cold head and the shields often used around the vacuum chamber to 70 – 100 K. Easily condensable gases, like water vapor, deposit on these outer pump stages. Argon condenses in the second stage. Hydrogen and helium bond to the activated carbon of the cold head by cryotrapping and cryoadsorption.

Formerly, cryopumps had been used only as high vacuum and UHV pumps due to their limited capacity for gas uptake. However, newer designs also permit their application in reactive vacuum processes such as thin film coating by cathode sputtering. This is done by partially throttling the pumping speed for process gases while maintaining full speed for water. Here, cryopumps have entered suc-

cessfully into competition with turbomolecular pumps. Standard sizes have pumping speeds from 1200 – 180 000 m^3/h. Special designs for space simulation chambers or for fusion experiments reach 1.8×10^8 m^3/h [42]. Pump speeds of this large order of magnitude can only be realized economically with cryopumps. For lower pump speeds in the high vacuum region, cryopumps should be compared with others, for example, oil diffusion pumps. The expense of the consumption of working fluid and cooling media as well as the problems associated with waste disposal might soon exceed the higher investment cost of a system with cryopumps.

3. Vacuum Diagnostics

One measure of the state of the gas in a vacuum unit is the total pressure, the sum of all partial pressures of the individual gases. Others of great interest are the gas composition and the partial pressures. Just as in the case of producing a vacuum, in regard to vacuum diagnostics, no one single measurement principle suffices to describe the whole range of particle densities understood under the term vacuum.

3.1. Total Pressure Measurement

In principle, measurement of total pressure may be handled in accordance with the basic fundamentals expressed by Equation (3), directly measuring the quantity *force/area*. Beyond that, a multitude of pressure-dependent physical quantities are well suited to indirect measurement. However, many of these effects are dependent on the nature of the gas [43]. The instruments are then calibrated for air or nitrogen; for other gases, the pressure must be determined by use of correction factors. Important points to consider in applying instruments for total pressure measurement are the measurement range, sensitivity, signal accuracy, and reproducibility. The measurement range Δp and sensitivity ("pointer movement"/δp) may depend on the nature of the gas. Accuracy and reproducibility are inherent aspects of each instrument.

Vacuum meters may measure either the absolute pressure directly or a differential pressure referred to a preset vacuum. Certain measurement principles are customarily used in the case of each of the individual pressure regions (Fig. 15). Rough and medium vacuum, and the viscous flow regime, are the domain of pressure measurement based on mechanical phenomena. In the medium and high vacuum regimes, the transition region between viscous and molecular flow, pressure measurement may rely on transfer of heat and momentum. Gas ionization effects are the measure of total pressure in the HV and UHV regimes, the regions of molecular flow.

3.1.1. Mechanical Vacuum Instruments

Mechanical vacuum gauges directly record the force acting on a membrane or on the surface of a liquid or solid body, $p \cdot A$ (Eq. (3)). In principle, they can also be used as *manometers* in the positive pressure region. Fundamental examples are the U-tube and the compression vacuum gauges. The former measures the difference between the pressures on a liquid in both the legs of a tube bent into the shape of a U. In the latter, a well-known design being the McLeod gauge, mercury columns compress a volume V_1 at pressure p_1 to a known volume V_2. From the now measurable pressure p_2, p_1 may be calculated using Equation (1). The measurement range of accurate compression vacuum gauges extends to 10^{-6} mbar. The measurement error is highly dependent on pressure regime and is $\geq 5\,\%$ of the measured value. U-tube and compression vacuum gauge measurements do not depend on the nature of the gas. However, the compression vacuum gauge is unsuitable for measuring the pressure of gas mixtures containing portions of condensable vapors.

Bourdon tube vacuum gauges represent a group of mechanical instruments based on the principle of a capsule or a hollow spring. They are used in the rough vacuum regime. Pressure-dependent motion of the capsule or spring is transmitted by a mechanical linkage to move the indicator pointer. Units designed to the precision required for purposes of calibration reach an accuracy of 0.3 % of scale value in the vacuum range 0.1 – 1000 mbar.

The use of mechanical-electrical transducers permits digitizing of the signal output, indication remote from the point of measurement, and high accuracy. The physical phenomena include

Figure 15. Pressure ranges of vacuum gauges [44]
Range of measurement with special design or with particular operating data

resistance changes in strain gauges, the piezoelectric effect, and measuring the electrical capacitance changes on deforming a membrane. Very sturdy and also corrosion-resistant designs are commercially available as pressure sensors in various sizes for pressures from one mbar to quite high positive pressures. The most accurate mechanical vacuum-measuring instruments are those based on measuring capacitance. They are available for measuring in the range 10^{-5} – 1000 mbar with a pressure-dependent minimum uncertainty of 0.05 % of the measured value.

Control of rough and medium vacuum pressures without high accuracy requirements employs the simple, problem-free, and inexpensive mechanical instruments. Capacitive pressure measurement suffices for high accuracy measurement, independent of the nature of the gas, e.g., for process gas control in the transition range between medium and high vacuum. In addition, capacitance vacuum gauges serve as transfer standards for calibration of measurement instruments in the pressure range 0.001 – 1000 mbar.

3.1.2. Viscosity Vacuum Gauge

The viscosity is pressure-dependent in the region where $d \leq \bar{l}$. The viscosity gauge uses this effect for pressure measurement. The momentum transfer described by the coefficient of external friction on a moving body retards it. Commercial devices consist of a freely-suspended sphere set into rotation in a magnetic field [45]. The instrument measures the pressuredependent decrease in the frequency of rotation due to friction. Figure 16 shows a pressure measuring head. The measurement range for this friction vacuum gauge extends from 10^{-7}–10^{0} mbar. The electromagnetic drive rotating the sphere produces a null effect, which determines the lower limit of the pressure range [46]. At high pressures, the restrictive factor is the change to a viscosity independent of pressure (Eq. (13)). Three factors combine to make this instrument an ideal standard for pressure measurement in the medium and high vacuum regimes (10^{-2}–10^{-6} mbar):

1) Accuracy of 1.5 % of the measured value
2) Long term stability, deviations <1 %/a
3) Calculation of the pressure measured requires only sphere diameter, sphere density, temperature, and frequency, all relatively easy to determine.

Figure 16. Sensor head of the spinning rotor gauge [45]
a) Rotor; b) Coils for pickup and control of axial rotor position; c) Coils of lateral damping system; d) Pickup coils; e) Permanent magnet; f) Drive coil; g) Vacuum enclosure

Further applications are direct measurement of the flow of gases from gas control instruments or desorbed from surfaces [47].

In the viscous flow region from 10^{0} – 10^{3} mbar, instruments also depending on gas friction are available for pressure measurement [48]. These utilize a second order influence on the resonance frequency of a quartz oscillator.

3.1.3. Thermal Conductivity Vacuum Gauge

A large variety of instruments utilize thermal conductivity to measure vacuum. Thermal conductivity depends on the pressure and nature of the gas. In principle, the rate of withdrawal of energy from an electrically-heated wire serves as the gauge of pressure. In practice, one measures the hot wire temperature thermoelectrically or by means of the resistance. Bridge circuits compensate for temperature deviations from a set value. The compensation serves as the measured variable and is related to pressure (Pirani principle). Utilizing convection allows extending the

range of reliable measurement into the viscous flow regime.

Heat losses from the lead wires and by radiation, which eventually outweigh heat transfer through the gas, result in a lower limit to the vacuum that can be measured. Therefore, thermal conductivity vacuum gauges have a measurement range of 10^{-4} – 10^{3} mbar. The calibration is done with air. The accuracy is ca. 20 % of the indicated value. Thermal conductivity vacuum gauges are simple, reliable, and inexpensive, and thus appropriate if extremely accurate measurements are not required.

3.1.4. Ionization Vacuum Gauge

The ionization vacuum gauges infer the pressure by measuring the stream of gas ions produced by electron collision ionization. Either of two methods are usual for producing the electrons necessary for gas ionization: an independent gas discharge (cold cathode ionization vacuum gauge) or glow emission of a heated wire (hot cathode ionization vacuum gauge). The measurement with either gauge depends on the nature of the gas. These gauges are usually calibrated with nitrogen.

The Penning vacuum gauge is the original, well-known form of the cold cathode vacuum gauge. It consists of two cathode sheets with a ring-shaped anode lying in between. A magnetic field in the direction of the electrode arrangement, produced by permanent magnets, amplifies the high voltage gas discharge by prolonging the electron paths. The discharge current is pressure-dependent over a broad range. Measuring tubes are available for the range 10^{-2} – 10^{-10} mbar. The measured value may be inaccurate by about a factor of two. However, this is scarcely a concern if the use of the Penning tube is limited to rough survey measurements. This kind of application is favored also by its extraordinary sturdiness and resistance to damage by sudden air break-in.

The underlying principle of the Penning gauge is the same as that for the ion getter pump. Just as the discharge current of the ion getter pump can serve as a pressure indicator, the Penning tube possesses a significant pump speed for gases, a possible cause for error in measurements.

The hot cathode vacuum gauge is built as a triode. A central glowing cathode emits electrons, which are accelerated to a concentrically-arranged anode grid. The positive ions produced by inelastic electron collisions give rise to a current to an ion collector located outside (Fig. 17 A). The ion current is directly proportional to the pressure and to the electron current:

$$i_{+} = C \cdot i_{-} \cdot p$$

The sensitivity C depends on the type of gas (tabulated for the common gases). At high pressures, C shows a maximum: measurement is no longer clear-cut. At low pressures, an ion current liberated by a photoeffect dominates (Roentgen limit). The Bayard – Alpert gauge (Fig. 17 B) shifts the Roentgen limit to lower pressures. This construction is a departure in which the ion collector, a fine wire, is in the center with a glowing cathode outside of the grid anode. Modulation of the ion current or extraction out of the ionization zone are further possibilities for broadening the useful range of measurement. For the conventional triode arrangement, the range is 10^{-1} – 10^{-6} mbar. The lower limit of the Bayard – Alpert gauge is 10^{-10} mbar. Commercial modulation tubes and extractor systems extend the range below 10^{-12} mbar. Special designs permit measurements below 10^{-13} mbar [49].

Figure 17. Principles of the A) triode gauge and B) Bayard – Alpert gauge

The potential measurement error of hot cathode vacuum gauges is about 10 % of the indicated value. In contrast, these gauges are sensitive to air break-in or to corrosion by gases. Especially in UHV applications, one must guard against a number of potential upsets [18]. Special ionization vacuum gauges equipped with gold electrodes are extremely stable and reproducible and are used as transfer standards for the range 10^{-4} – 10^{-9} mbar.

3.1.5. Measuring Systems

Frequently, vacuum gauges producing an electrical signal are combined with an electronic unit to create a measuring system. By automatic switching among the several devices, the entire pressure range can be measured. For process control, several pressure-dependent switch points are often available. In addition to the analog output always provided by pressure recording, more complex instruments provide computer-compatible outputs for remote control and readout.

3.2. Partial Pressure Measurement

Detection of the individual gas components and measurement of their partial pressures with a mass spectrometer offers substantially better insight into the nature of a vacuum than the total pressure.

Mass spectrometers consist of the following:

1) A gas ionization device
2) A separation system, which sorts the ions produced, mostly in accord with their charge/mass ratio
3) An ion detection apparatus
4) Control, evaluation, and indicator electronics

The gases are ionized, analogous to the operation of the glowing cathode vacuum gauge, by ionizing collisions with electrons from a glowing cathode. A focused beam of ions issues from the ionization zone and is directed into the analyzer section. For separating the ions, two principles are in widespread use: separation with a magnetic sector field and filtration by an electrical quadrupole field. In units with a magnetic sector, the ion beam is accelerated by the potential difference U, and then traverses a sector-shaped magnetic field perpendicular to the beam direction (Fig. 18 A). By this means, ions with the path radius r are diverted, where:

$$r = \vec{p} \,/\, (B\,q)$$

and

B = magnetic flux density
q = the ionic charge
$\vec{p} = m\ \vec{v}$ = the momentum of an ion

Figure 18. Partial pressure analyzers
A) Magnetic sector type [50]
a) Ion source; b) Beam of positive ions; c) Entrance slit; d) Magnetic field (points out of page); e) Exit slit; f) Detector; g) Ion acceleration region
B) Quadrupole type [51]
a) Cathode; b) Electrons; c) Ion beam

At constant U, the relation:

$$r \sim \sqrt{m/q}$$

is valid. If an ion detector is located at a fixed point at the outlet of the magnetic sector, then, by varying B or U, the gas ions can be sorted according to their ratio m/q and recorded.

In quadrupole mass spectrometers, the separation system consists of four, equally spaced rod-type electrodes (Fig. 18 B). In most cases, cylindrical electrodes approximate the ideal hyperbolic form. Between the respective opposite pairs of rod electrodes, a direct voltage is applied, with a high frequency alternating voltage superimposed. Ions shot axially into the electrode system experience transverse oscillations in the alternating voltage field. Thus, only ions with a certain ratio m/q can leave the filter system without touching the electrode surfaces and being neutralized. One may vary the ratio m/q to

obtain a linear mass scale by holding frequency constant and changing the direct and alternating voltage amplitudes.

The resolving power, $m/\Delta m$, measures the quality of the separation system. According to the convention, two equally high mass peaks are said to be separated if the height of the valley between both the peaks is lower than 10 % of the peak height. With both types of analyzer, this "unit resolution" can be met or exceeded for the range of mass between one and >500 amu (atomic mass unit).

The ions are detected either directly as an ion current by a Faraday collector or are converted into secondary electrons and amplified in a secondary electron multiplier. When high detector sensitivity is required, the arriving ions are counted as individual impulses with the secondary electron multiplier. The detector limits for partial pressure lie at 10^{-10} mbar for Faraday collectors, $<10^{-14}$ mbar with the secondary electron multiplier, and in the range of 10^{-16} mbar for individual counting.

Mass spectrometers with magnetic sectors require only simple electronic provisions. Thus, they achieve high detector stability. Disadvantages are the magnetic field, which can be the cause of breakdown, and the resolving power, which is controlled mechanically by means of the inlet and outlet slits.

More than 95 % of all installed mass spectrometers are now of the quadrupole type. This is a consequence of the broad development of control and readout devices made possible in combination with microelectronics. However, above all, the stability of units equipped with a secondary electron multiplier is only good enough for use as a process controller with great expense for calibration. Thus, the principal fields of application are the analysis of gas mixtures and the diagnosis of vacuum systems. Mass spectra show the ionic current as a function of the mass from the heights of the individual peaks. However, errors may arise: on the one hand through the probability of ionization of the gases in question, and on the other hand through the possible occurrence of several ionized species having equal q_1/m_1 ratios or of ionic fragments having the same charge q and mass m but a different composition. Ionization factors for ions and ionic fragments of gases must be taken from tables or catalogs of spectra [52–54].

Figure 19. Mass spectra recorded by a simple quadrupole mass spectrometer (different pressure scaling!)
A) Mass spectrum of air at $p = 2\times10^{-4}$ mbar
B) HV-plant, strong water adsorption at the walls $p_{\mathrm{total}} = 3.8\times10^{-5}$ mbar
C) HV-plant, thouroughly degassed, $p_{\mathrm{total}} = 4.5 \times10^{-8}$ mbar

If all these influences are considered, a process of calculation can derive the accurate value of a partial pressure from the mass spectra. Figure 19 shows three typical quadrupole mass spectra:

1) The spectrum of air at 2×10^{-4} mbar, the ratio $p_{(\mathrm{N_2})} : p_{(\mathrm{O_2})} = 5$ is characteristic (Fig. 19 A)
2) The spectrum of an unheated high vacuum system, the water peak dominates (Fig. 19 B)
3) The spectrum of a well-heated high vacuum system, H_2 and CO_2 are represented with heavy lines, the background noise of the spectrometer is already relatively high (Fig. 19 C)

Figure 20 shows the spectrum of a system contaminated with forepump oil. The occurrence of a series of various ion fragments differing the mass of the group "$-CH_2-$" is typical.

Figure 20. Mass spectrum of a HV-plant contaminated with rough pumping oil, $p_{\mathrm{total}} = 2.4 \times 10^{-5}$ mbar

Modern quadrupole mass spectrometers possess either electronically stored mass spectra of frequently occurring gases or determine the partial pressures using fixed, built-in evaluation programs. Connected to an external computer, mass spectrometers can mostly operate under program control. For evaluating the spectra, extensive programs are available. Simple vacuum diagnosis spectrometers record the masses 2 – 50 (100); the mass scales of routine equipment reach from mass one – 100 (200); research equipment measures out above mass 200.

Mass spectrometers can be applied directly only to pressures $\leq 10^{-4}$ mbar. Adding commercially available pump systems enables the region to and above atmospheric pressure to be attained. In these, restrictions independent of molecular mass produce the necessary pressure drops.

3.3. Leak Surveys

The term *leak* is understood to mean local breaches in the tightness of the vacuum container through which the gas can penetrate from outside into the vacuum. One must distinguish the gas streams caused by desorption or permeation from those resulting from the leak condition. It is not possible to avoid leaks completely. Leaks increase the oxygen partial pressure in the system. One must estimate how much the effect of leaks disturbs the system operation to determine the extent to which it is necessary to remove the leaks. The tolerable leak rates depend above all on the range of vacuum being used. Even when working with process gases in the medium vacuum area, a very low residual gas pressure, when important for the process, may also make necessary the removal of leaks to a degree that would impair the pump-out operation only in high vacuum.

For leak surveys including determining leak rates and locating leaks, various procedures have been developed which work with and without a test gas. In the rough vacuum regime, a direct determination of the leak rate is possible through measuring the gas flow discharged from the pump. One may fill the vessel to be tested with gas to positive pressure or evacuate it. Then, one can calculate the leak rate, q_{L}, through the drop or rise in pressure, Δp, with regard to the vessel volume V by:

$$q_{\mathrm{L}} = V \cdot \Delta p / \Delta t \tag{22}$$

The slope of the plot of pressure versus time permits distinction between desorption (initial high $\Delta p/\Delta t$) and leak rate (constant lower $\Delta p/\Delta t$ after a longer time).

Leak search methods involving test gases take substantially less time, and desorption is not a factor. The unit to be tested is filled with the test gas, traces of which outside the container are used to find the leak location. Or, by placing the unit full of test gas inside a vacuum container, measurement of the overall test gas flow into that container is possible. These methods are useful only with sealed vacuum containers, for example, with relay tubes. Filling can be done by storing the test unit in test gas under positive pressure.

In a second procedure, one can expose the test container, which is under vacuum, to the test gas on the outside either locally, at the place suspected of leaking, or globally, in a vessel enclosing the test container. Special leak-testing instruments detect the test gas flowing into the leak. Halogen leak detector instruments use a heated platinum-covered surface as a sensor emitting alkali-metal ions. The ion current increases greatly due to the effect of the halogen-containing gas; chlorofluorohydrocarbons are normally used. Leak rates $q_{\mathrm{L}} \geq 10^{-6}$ mbar L/s can be detected.

Helium leak detectors are more sensitive. With helium as the test gas, detection of leak

rates to 10^{-11} mbar L/s is possible. Helium leak detectors include a mass spectrometer with the magnetic sector adjusted to a fixed mass of four. Usually, they are also adjustable to the masses three and two. An integrated pumping system supplies the necessary vacuum, lower than 10^{-4} mbar, in the mass spectrometer. The helium leak detector can be flanged directly to the vacuum vessel to be checked. It is also possible to suck gas through a suction duct from the vessel surfaces to the mass spectrometer (sniffing method). Helium leak detectors are thoroughly automated. Self-acting range adjustment, background correction, and devices for programmed control of the components of a vacuum system are state of the art.

4. Vacuum System Components

To a large extent, vacuum units can be assembled from standardized parts in accord with the principles of modularization. Only the vacuum chamber must be fabricated to suit the particular purpose. The necessary piping, flanges, erection materials, and shut-off devices are available in standard sizes [55]. Transition pieces between particular standard sizes, as well as between different flange systems, are offered in all variations. Therefore, the exchange of parts for the vacuum unit offers no special problems, either within a series from the same manufacturer or from other fabricators.

4.1. Piping Components

Piping components are pipes with both ends flanged, pipe stubs with flanges, crosses, tees, elbows, transition pieces between various standard sizes or between different flange systems and glass-to-metal connections. Spring supports and expansion joints of plastic and metal serve to isolate movement and vibration. Piping components of nominal sizes between 10 and 50 mm are available in glass-fiber-reinforced plastic, aluminum, or stainless steel. The engineering properties for vacuum service improve and the corrosion resistance, mechanical strength, as well as price increase from plastic to aluminum to stainless steel.

Flanges with gaskets between them connect the piping components. There are three common types of flanges, the small flange, the clamped flange and the CF flange (Fig. 21). Joints with small flanges in nominal sizes between 10 and 50 mm are held together by clamp rings or linked rings operable with one hand. They are sealed by centering rings containing round gaskets (“O” rings) made of butyl rubber or fluorocarbon ruber (“ Viton”). For applications requiring corrosion or heat resistance, or for other special purposes, many more gasket materials are available, including silicon rubber, Kalrez, PTFE-coated silicon rubber and nickel-powder-filled PTFE (TENIC). Sealing disks of pure aluminum are also used. With flawless seal surfaces and gasket rings, greasing with vacuum grease is not necessary. Greasing will not achieve greater tightness of the flanged joint.

The leak rate for small flange joints is $<10^{-8}$ mbar L/s, and yet an order of magnitude less with aluminum gaskets. With metal gaskets, small flanges can be heated to 200 °C. The field of application ranges from high vacuum to low positive pressure.

Clamped flange joints in nominal sizes from 65 to 500 mm show engineering properties for vacuum similar to those for small flanges. The joint and the necessary sealing pressure are produced by a number of clamp screws (PNEUROP clamp flanges) suitable for the particular size. Another type uses cap rings bolted together (DIN flanges and PNEUROP cap ring flanges).

CF flanges are used for UHV applications. Rings of pure copper (OHFC copper), or Viton for lesser requirements, serve as gaskets into which the stainless steel knife edges of the flange are pressed. These flanges, in nominal sizes from 16 to 250 mm, have leak rates $<10^{-10}$ mbar L/s, and can be heated to 500 °C. Larger UHV flanges, in nominal sizes to >1000 mm are built similarly; moreover, gasket wires of silver and gold are also employed.

Various clamp ring systems using screwed caps (Fig. 22) are preferred for tubing joints with sizes ≤10 mm. They are manufactured using stainless steel and various plastics. Stainless steel joints of this type are not only suitable for high vacuum but are also pressure-tight to several bar.

Figure 22. Threaded tube connection

4.2. Vacuum System Feedthroughs

A great variety of vacuum feedthroughs for all vacuum regimes permit control of experiments and manipulations in vacuum containers. These include:

1) Glass view ports, also of UV- and IR-transparent materials for optical measurements
2) Thermocouple feedthroughs
3) Leadthroughs for liquids
4) Electrical feedthroughs for measurement or for load ratings up to 5000 A or up to 20 kV.

Motion feedthroughs capable of turning or linear movement can serve as manipulators or permit built-in drives. They can be applied to the HV region with O-ring seals. They are suitable for the UHV region if the movement is transferred either by means of a spring bellows sealing mechanism or with magnetic liquids. Figure 23 shows an example of the abundance of possible components.

Figure 23. Leadthrough for transmission of rotary and linear motion [56]

4.3. Valves

Figure 24 shows the valves used as shutoff or lock devices between parts of vacuum units for gas inlet, gas control, throttling, and venting services. According to the design of the body, one makes a distinction between throughflow valves, with connecting flanges located on the valve axis, and angle valves, whose flanges form a right angle with one another. Valves of nominal sizes to 160 mm are operated manually; or, magnetic, electric motor, pneumatic, and hydraulic drives are available.

High vacuum valves are sealed with butyl rubber or Viton rings. Valve seats made of metal or ceramic must be used in UHV applications. Spring bellows usually separate the top works from the vacuum side. Springs, the drive mechanism, or the help of atmospheric pressure produce contact pressure on the seat. However, valves are preferred in which both sides of the seat close tight against the atmosphere. The valve function takes place by raising the valve

disk through a rotating gate (butterfly valve) or sideward motion or linear withdrawal (slide valves). The mechanisms are so designed that no sliding motion takes place on the seats. As with every additional component in a piping system, valves reduce the conductance, angle valves more intensely than throughflow valves, and also possess an unavoidable leak rate.

Isolating valves are available in nominal sizes from 10 to >1000 mm. In general, they are meant for operation in the fully open or fully closed positions. They are switching devices for individual pipes or shutoff devices for system components. In the form of special designs to suit a special purpose, they are also installed as locks for loading and unloading vacuum chambers. Simple isolating valves of small size serve as venting valves for admitting air into the system. So-called quick closing valves protect larger systems from air break-in by partitioning off the leaking portions of the system (Fig. 25). Gas admittance or regulating valves can be adjusted reproducibly to positions between on and off. In these, the position of a valve plug of varying diameter relative to a conical valve seat is changed to vary the valve port area, and thus conductance. Regulating valves are available with gas flow rates of 10^{-10} – 10^{3} cm^3/s, either hand-operated or electronically adjustable. At higher rates, the gas inflow can be handled with gas flow control instruments, largely independent of the pressure difference. A signal proportional to the gas flow, measured in a side stream conduit by a sensor system that depends on thermal conductivity, is the control variable for an electrically-operated valve. By this means, commercially available instruments control gas flows between $<10^{-3}$ to $>10^{5}$ cm^3/s with high accuracy and reproducibility. Either calibration or correction factors take into account the gas dependency. These are entered into the control instrument or are already stored there electronically and called up as needed. Conductance controllers using adjustable iris shutters or adjustable louvers regulate the vacuum process pressure and gas throughput. This allows adjustment of the vacuum system to the pumping speed of the pump system.

If a vacuum system is to be automated, then electrically-controlled valves can be used to do it. When these valves are equipped with valve position indicators, they provide the necessary signals indicating the switch position status needed for process system automation.

5. Vacuum System Applications

The applications of vacuum technology are numerous and a few fields of application are discussed here. Vacuum technology is used in preparation and processing of materials–for drying, freeze-drying, impregnating, distilling, modern welding procedures, remelting metals, production of metal powders, crystal pulling, and for degassing a wide range of materials. The foodstuff, pharmaceutical, metallurgical, and electronic industries have developed equivalent processes.

Manufacturing certain products from component parts can be done successfully only under vacuum. Examples of this are found in producing thin film surface coatings with thicknesses in the µm range for the electronic, optical, and tool industries. Vacuum switches, cathode ray tubes, transmitting tubes, and incandescent bulbs require vacuum for their operation. Modern physical surface analysis methods make use of vacuum technology, for example, in electron microscopy, and various other excitation and detection mechanisms. These permit conclusions to be drawn on the structure, composition, and state of the chemical bonds of solid surfaces. Particle accelerators, storage rings, nuclear fusion research plants, and space simulation belong to the most extensive scientific applications of vacuums.

Vacuum has an important industrial significance–here the term negative pressure is preferred–in conveying equipment for moving paper in printing machines, for moving plate-like loads, and for conveying granulated materials or liquids.

5.1. Perspectives on Design of Vacuum Systems

The working pressure p_W determines the design of a vacuum system. The following equation expresses the relationships between p_W, p_E, the ultimate pressure attainable by the pump system, and the gas flows shown in Figure 26:

$$p_W - p_E = (q_D + q_A + q_P + q_L + q_F)/S_{eff} \quad (23)$$

where

q_D = flow arising from desorption
q_A = flow arising from absorption
q_P = flow arising through permeation
q_L = flow arising through leakage into the system
q_F = flow originating in the process
S_{eff} = effective pumping speed at the vacuum receiver

Figure 26. Gas throuphput of a vacuum chamber (see text for explanation of symbols)

Nearly all quantities on the right-hand side of Equation (23) are temperature- and pressure-dependent and thus, indirectly, a function of the sequence of the vacuum process. From this results the timedependence of the working pressure p_W. For estimates, the relationship shown by Equation (23) may be simplified. Thus, for working in the rough vacuum region, one may neglect desorption, absorption, and permeation and can concentrate, for example, on the leak rate for a given pump size. By comparison, for operations in the UHV region, q_L (and q_F) are normally negligibly small, and the importance of the quantities q_D,

q_A, and q_P is enhanced.

The economy of a vacuum system improves with careful adjustment of the effective pump speed S_{eff} to the system's requirements. The individual pump stages consisting of various pump types, which must be installed to work over wide ranges of vacuum, must also be suited to one another. The right choice of pump types and sizes can minimize investment costs and energy requirements. The choice of individual pump types and the components of a vacuum system must suit the anticipated working pressure and correspond to the nature of the vacuum process. In this, quantity and nature of the gases at hand, corrosion properties, presence of condensibles, entrainment in the form of liquid drops or solid particles are important. Factors assuming

even greater importance in conceptual design of vacuum systems are environmental impact and waste disposal problems. Above all, increased quantities of cooling water, or systems not having closed recycle loops for working fluid supply, cause additional burdens on the required environmental protection system. Necessary disposal of old oil and process-derived waste products is difficult and may act as a significant cost factor.

5.2. Examples of Vacuum Systems and Their Application

5.2.1. Decontamination of Groundwater

The careless handling of chlorinated hydrocarbons has in many cases led to contamination of the soil and the groundwater. Drawing air from wells through the ground represents one possible way to remove this pollutant. Blowing oil-free compressed air through the soil brings a further improvement in the groundwater ("in-situ stripping") [58].

Depending on the condition of the soil, the process requires pumping of 600 – 700 m^3/h at low pressure differences of 10 – 200 mbar. Beside the pollutant portion of up to 14 kg/h of chlorinated hydrocarbon [59], the pumped air may contain high amounts of water vapor and solids. Thus, this service requires a rugged vacuum pump having a low compression ratio and high pump speed in the rough vacuum region. In addition, these installations often include necessary separator equipment for sand on the suction side and filters with activated carbon on the discharge side for the hydrocarbons.

Problem-free, simple vacuum systems which fulfill these requirements may be assembled using, for example, gaseous ring pumps. Since they run dry, these offer no working fluid or lubricating problems. Technically, they are very simple and thus ideally suitable for mobile units to be set up at the polluted site.

Systems of this kind have been installed and operate successfully. They result in considerable savings compared to conventional methods of decontamination, as for example, excavation and removal of the soil.

5.2.2. Degassing Steel with a Steam Jet Vacuum System

Degassing molten steel takes place at a pressure of 0.5 mbar for which pump speeds to $>10^6$ m^3/h are necessary. The resulting dust is pyrophoric in air and must, therefore, be removed safely. Figure 27 shows a steel degassing unit using a three-stage steamjet pump installation to produce vacuum. Highest speed steamjet pumps are manufactured at competitive prices. Their operation is completely unaffected by dust in the suction gas. Pump stages a_1 and a_2 are directly connected one to another in series and compress to a pressure which permits condensation of the motive steam in the barometric condenser b_1. The pyrophoric dust is washed out by stream condensation and settles in a sedimentation basin. After pump stage a_3, the residual gas is purified in b_2 by the remaining dust. Lastly, the liquid ring pump d compresses the residual gas to atmospheric pressure. Residual operating liquid and condensate are led back, via the last separator b_3, into the cooling cycle. A cooling tower cools the condenser cooling water to close the circuit permitting water reuse with minimal environmental impact. The only condensate produced is condensed motive steam. The washing effect of the barometric condensers results in extensive removal of pollutants from the residual gas.

5.2.3. High Vacuum Systems for Manufacturing Thin Films

Vaporization and deposition by means of cathode sputtering are vacuum operations for producing thin films on substrates in the thickness range up to 10 µm. The palette of uses for these films includes the following: decorative films, optical films, mirror coatings on projector reflectors, heat-reflecting coatings on window glass, resistance films, electrode coatings for foil condensers, coatings for semiconductor components, tribologically-effective surface layers for dry lubricant coatings, and wear-protective coatings. It is possible to coat surfaces not only with metallic layers, but by carrying out reactive processes, with oxides, nitrides, and layers of other compounds.

Figure 27. Degassing of steel with vapor jet vacuum pumps [60]
a_{1-3}) Vapor jet pumps; b_{1-3}) Condensing devices; c) Dust sedimentation; d) Liquid ring pump; e) Heat exchange

The basic principle of the vacuum system required for this is the same for all applications: a titanium nitride protective coating, for example, is deposited reactively by dispersing a titanium cathode in a nitrogen-containing gas discharge. The gas necessary for sputtering is a mixture of argon with a partial pressure of about 0.01 mbar and nitrogen at about 10^{-4} mbar partial pressure. Water vapor is decomposed in the gas atmosphere and the oxygen is incorporated into the resulting surface layer. To avoid producing this oxynitride film, it is necessary to reduce the water partial pressure to a value substantially below that of the nitrogen. The vacuum technology prerequisite, therefore, is a high vacuum system with an ultimate pressure in the 10^{-7} mbar range and with sufficient pumping speed, yet at 0.01 mbar suction pressure. These requirements are best resolved with a high vacuum pumping installation using a turbomolecular or a cryopump, as shown in Figure 28, as the high vacuum stage.

Figure 28. High vacuum plant–principle (see Fig. 2 for explanation of graphics)

The evacuation step proceeds in the customary way under automatic control. First, with valves V_1 and V_3 closed, the receiver is evacuated to a pressure that depends on the type of high vacuum pump. Then, with V_2 closed and V_1 and V_3 open, the receiver is evacuated to the ultimate pressure. V_4 can be used to vent the receiver. Gas flow controllers (C) regulate the inflow of process gas. Vacuum measuring points M_1 and M_2 indicate the pressure at the receiver and the vacuum produced by the forepump. While valve V_3 is necessary if one uses oil diffusion pumps, it may not be needed with turbomolecular or cryo-pumps.

At 0.01 mbar, tubomolecular and, particularly cryopumps possess sufficient pump speed compared to oil diffusion pumps, and permit pumping out to the desired high vacuum. At high gas pressure, the total pump speed of the turbomolecular pump must be throttled by a valve connected upstream. Whereas with the cryo-pump only the argon pumping speed for cryo-pump stage 1 need be reduced selectively via louvers, the water vapor pumping speed for pump stage 2 remains in full effect. Thus, low water vapor partial pressure is always assured, and the pump capacity for argon and nitrogen is preserved for hours or days.

The laboratory system corresponding to the flow scheme of Figure 28, when equipped with a refrigerator cryopump of 5400 m^3/h for air and a forepump of 60 m^3/h, has a potential operating cycle between regeneration steps of >15 h at 8×10^{-3} mbar argon pressure. The forepump is used only for pumping out the receiver after repressuring and for removing the melting gases during regeneration. To achieve short regeneration times, it is grossly oversized. During the making of the surface coating, the valve between the cryopump and forepump is closed and the forepump shut down.

The same scheme as that described for the laboratory system is used for the commercial system shown in Figure 29. It serves to deposit a layer of hard material on tools. With sputter cathodes of 1350×230 mm^2 and a substrate holder of 1050×600 mm^2 area, eight hours are needed to coat 6000 6-mm drills and 800 150-mm milling tools with a titanium nitride layer. An inlet lock chamber (a) and an outlet lock chamber (e) precede and follow the actual coating chamber (c), joined to them by lock valves (b). Movement of the substrate through the system is automatic; thus, the coating chamber is always held under vacuum. Rotary lobe, sliding vane pump combinations evacuate the repressured lock chambers at each loading-unloading cycle. These have high pump speeds up into the medium vacuum range. Eight turbomolecular pumps (only four are shown) with a total pump speed of 21 600 m^3/h maintain vacuum in the main chamber. The forepumps for these are again a rotary lobe/sliding vane installation.

Similar industrial vacuum systems, built mostly in modular fashion with chambers connectable to one another in series, are installed, for example, for coating plastic film with magnetic layers for storage media or for coating architectural glass of up to 3×6 m^2 with heat barrier layers.

5.2.4. Ultra High Vacuum System for the LEP Storage Ring at Geneva

At CERN in Geneva, the storage ring for the LEP machine (large electron positron collider) has been built for conducting electron-positron scattering experiments [54], [62]. In the final design, electron and positron energies exceeding 90 GeV should be possible. The storage ring, in the form of an octagon rounded at the corners, has a length of 27 km. An average pressure of 4×10^{-9} mbar is necessary to enable a beam lifetime, determined by the residual gas, of >20 h. This requires a base pressure $<10^{-10}$ mbar without the electron beam and also in some individual compartments with the beam.

In operation, the residual gas arises, above all, through photodesorption caused by the intense synchrotron radiation. This is incident on a strip of the beam tube wall only a few millimeters wide with a specific power of 1.4 kW per meter of beam tube length. A big part of this energy must be withdrawn as heat. For this, water-cooling ducts are required next to the beam tube. The beam tube has an elliptical cross section of 131×70 mm. This cross section has been greatly reduced from that possible by applying accelerating and focussing electromagnets.

Special concepts for materials and pumps are necessary to fulfill the catalog of these requirements and properties. The vacuum system

Figure 29. High vacuum thin film production plant [61]
a) Input vacuum interlock; b) Valves; c) Sputtering chamber; d) Cathodes; e) Exit vacuum interlock

must be built to meet the specifications for full UHV operation. This means materials suitable for high-temperature operation and metal seals. The beam tube is flanged together from separate pieces of length suited to the various magnets. Because of its good thermal conductivity and ease of fabrication, an aluminum alloy is used; it is extruded in the shape of the vacuum chamber cross section shown in Figure 30. Next to the elliptical cross section of the beam tube, one recognizes the three cooling ducts. In addition, there is the rectangular pump duct connected to the beam tube through slits.

A getter pump (NEG pump) with a total length of 20 km connects to the pump duct. This pump, distributed over the whole ring, removes the gases produced directly at the locations where they occur. The NEG pump is a two-phase mixture of zirconium and 16 % aluminum pressed on both sides of a 30-mm wide constantan heating strip. This can be heated by direct current. After a 10-min activation at 700 °C, in which the gases chemically bonded to the getter surface diffuse into the interior, a pump speed of ca. $1000\,\mathrm{s}^{-1}\,\mathrm{m}^{-1}$ is achieved, which depends on the type of gas.

In addition to the NEG main pump for the reactive gases, 1800 ion getter pumps, each having a pump speed of $108\,\mathrm{m}^3/\mathrm{h}$, are installed for pumping the noble gases and methane. Finally, simple turbomolecular pump systems, having $500\,\mathrm{m}^3/\mathrm{h}$ speed, are used for pumping from atmospheric pressure to the high vacuum region, for leak survey work, and while the vacuum system is being heated up.

Figure 30. Cross section through the LEP vacuum chamber [63]
a) Lead shielding; b) Pump channel; c) Beam channel; d) Water cooling ducts

At least a twenty-year operating life is expected for the capacity of the NEG pump for the irreversibly bonded gases carbon monoxide and carbon dioxide at the planned operating times and parameters.

Symbols:

a specific contact area between reaction and nonreaction phase, m^2/m^3 dispersion

a_A chemical activity of component A, mol/m^3

a_g $= \frac{\lambda_g}{\varrho_g C_{p,g}}$; gas thermal diffusivity, m^2/s

a_{gl} specific gas – liquid interface area per unit of dispersion volume, m^{-1}

a_{ls} specific catalyst particle external surface area per unit of dispersion volume, m^{-1}

A_p pellet external surface area, m^2

Al $= \frac{(1-\varepsilon)\, k_{1,A}}{a \mathbb{D}_A}$; Hinterland ratio, ratio between total liquid-phase volume and liquid-phase stagnant film volume

An $= \frac{E_a}{\Delta T_{ad} R} Le^{2/3}$; modified Arrhenius number

b_A adsorption constant of component A for slow surface reaction and relatively fast ad- and desorption, Pa^{-1}

$b_{A,\infty}$ pre-exponential factor of b_A, Pa^{-1}

Bi_A $= \frac{k_{g,A} r_p}{\mathbb{D}_{i,A}}$; Biot number of component A used in the shrinking core model

$\cosh(u)$ hyperbolic cosine function: $\cosh(u) = \frac{e^u + e^{-u}}{2}$

C total molar concentration of the reaction mixture, mol/m^3

C_A concentration of component A, mol/m^3

$\overline{C_A}$ concentration of component A in well-mixed fluid bulk, mol/m^3

$C_{A,c}$ concentration of component A at core boundary in shrinking core model, mol/m^3

$\overline{C_{A,g}}$ concentration of component A in well-mixed gas phase bulk, mol/m^3

$C_{A,i}$ concentration of component A at interface, mol/m^3

$C_{A,in}$ concentration of component A in reactor inlet stream, mol/m^3

$C_{A,i,g}$ concentration of component A at gas – liquid interface on gas-phase side, mol/m^3

$C_{A,i,l}$ concentration of component A at gas – liquid interface on liquid-phase side, mol/m^3

$C_{A,i,s}$ concentration of component A at catalyst pellet external surface, mol/m^3

$\overline{C_{A,l}}$ concentration of component A in well-mixed bulk of liquid phase, mol/m^3

$C_{A,p}$ concentration of component A inside catalyst pellet with negligible intra particle concentration gradient, mol/m^3

C_{A0} liquid inlet concentration of component A for bubble column, mol/m^3

$C_{A,0}$ concentration of component A for zero conversion, mol/m^3

$C_A —_t$ concentration of component A at time t, mol/m^3

$C_A —_{t=0}$ concentration of component A at $t = 0$, mol/m^3

$C_A —_z$ concentration of component A at location z in plug-flow reactor, mol/m^3

$C_A —_{z=0}$ concentration of component A at $z = 0$ or at inlet of plug-flow reactor, mol/m^3

$C_{A,BR}(t)$ concentration of component A in batch reactor after reaction time t, mol/m^3

C_I initiator concentration, mol/m^3

C_M monomer concentration, mol/m^3

C_{MO} concentration of metal oxide in virgin ore for shrinking core model, mol/m^3

$C_{p,g}$ specific heat of the gas, $J\,kg^{-1}\,K^{-1}$

$C_{\mathrm{P.}}$ concentration of growing, free-radical polymer chains, mol/m^3

$C_{\mathrm{R.}}$ free-radical concentration, mol/m^3

C_{T} concentration of tracer material, mol/m^3

d_{b} gas bubble diameter, m

d_{S} $= \frac{\sum d^3}{\sum d^2}$; Sauter mean bubble diameter, m

Da $= \frac{kt}{C_{\mathrm{A,0}}}$ (BR), $\frac{k\tau}{C_{\mathrm{A}}|_{z=0}}$ (PFR), $\frac{k\tau}{C_{\mathrm{A,in}}}$ (CISTR and CSSTR); Damköhler number for zeroth-order kinetics

$\mathbb{D}_{\mathrm{A}}$ molecular diffusion coefficient of component A, m^2/s

$\mathbb{D}_{\mathrm{A,g}}$ diffusion coefficient of component A in gas phase, m^2/s

$\mathbb{D}_{\mathrm{fl}}$ diffusion coefficient in bulk of fluid, m^2/s

$\mathbb{D}_{\mathrm{i}}$ effective diffusion coefficient inside porous pellet, m^2/s

$\mathbb{D}_{\mathrm{i,A}}$ effective diffusion coefficient inside porous pellet of component A, m^2/s

$\mathbb{D}^{h}_{\mathrm{i,A}}$ effective diffusion coefficient in ring-shaped or cylindrical porous catalyst pellet in longitudinal direction, m^2/s

$\mathbb{D}^{*}_{\mathrm{i,A}}$ effective diffusion coefficient, modified for pellet anisotropy, m^2/s

$\mathbb{D}^{r}_{\mathrm{i,A}}$ effective diffusion coefficient in ring-shaped or cylindrical porous catalyst pellet in radial direction, m^2/s

$\mathbb{D}_{\mathrm{Kn}}$ Knudsen diffusion coefficent, m^2/s

$\mathrm{erf}\,(u)$ error function:

$$\mathrm{erf}\,(u) = \frac{2}{\sqrt{\pi}} \int_0^u \exp\left(-x^2\right) \partial x$$

E_{a} activation energy, J/mol

E_{A} $= \frac{\overline{J_{\mathrm{A}}}\ \text{with reaction}}{\overline{J_{\mathrm{A}}}\ \text{without reaction}}$; enhancement factor of component A

E_{A0} $= \frac{\overline{J_{\mathrm{A}}}}{k_{1,\mathrm{A}} C_{\mathrm{A,i}}}$; modified enhancement factor used, e.g., in Van Krevelen – Hoftijzer approximation

$E_{\mathrm{A}\infty}$ $= \left(1 + \frac{1}{\nu} \frac{\mathbb{D}_{\mathrm{B}}}{\mathbb{D}_{\mathrm{A}}} \frac{\overline{C_{\mathrm{B}}}}{C_{\mathrm{A,i}}}\right) \left(\frac{\mathbb{D}_{\mathrm{B}}}{\mathbb{D}_{\mathrm{A}}}\right)^n$; enhancement factor for case of instantaneous reaction

E_{+} activation energy for reaction to right-hand side, J/mol

E_{-} activation energy for reaction to left-hand side, J/mol

$E\,(t)$ residence-time frequency distribution as function of t, s^{-1}

$E\,(\theta)$ residence-time frequency distribution as function of θ

f initiator efficiency; for $f = 1$, all initiator decomposes to active radicals; for $f = 0$, no active radicals are formed at all

$F\,(t)$ $= \int_0^t E\,(u)\ \partial u$; cumulative distribution of residence times

h longitudinal coordinate, m

H (1) parallelepiped height, m
(2) height of Raschig ring, m

Ha Hatta number, measure of square root of reaction rate divided by rate of mass transfer of component A; exact definition depends on kinetic expression

Ha_{i} modified Hatta number for reactions between reactants from a gas and a liquid, based on liquid-phase reactant interface concentration $C_{\mathrm{B,i}}$ (usual Hatta number is based on bulk concentration $\overline{C_{\mathrm{B}}}$)

$(-\Delta H_{\mathrm{ads}})$ adsorption enthalpy of component A on chemically active catalyst surface; since adsorption is an exothermic process, $(-\Delta H_{\mathrm{ads}}) > 0$, J/mol

$(-\Delta H_{\mathrm{r}})$ reaction enthalpy; for exothermic reactions, $(-\Delta H_{\mathrm{r}}) > 0$; for endothermic reactions, $(-\Delta H_{\mathrm{r}}) < 0$, J/mol

$\mathrm{I}_0\,(u)$ zeroth-order modified Bessel function of the first kind: $I_0\,(u) = \sum_{i=0}^{\infty} \left(\frac{u^i}{2^i\, i!}\right)^2$

$\mathrm{I}_1\,(u)$ first-order modified Bessel function of the first kind: $I_1\,(u) = \frac{u}{2} \sum_{i=0}^{\infty} \frac{(u/2)^{2i}}{i!\,(i+1)!}$

J_{A} molar flux of component A through interface, mol m^{-2} s^{-1}

$\overline{J_{\mathrm{A}}}$ average molar flux of component A for contact time τ of a stagnant fluid element in penetration theory, mol m^{-2} s^{-1}

$J_{\mathrm{A,p}}$ molar flux of component A at pellet external surface, mol m^{-2} s^{-1}

$(J_{\mathrm{A}})_{\mathrm{phys}}$ molar flux of component A through interface if no chemical reaction occurs, mol m^{-2} s^{-1}

$(J_{\mathrm{A}})_x$ molar flux of component A at location x, mol m^{-2} s^{-1}

$J_{\mathrm{A}}(r)$ molar flux of component A at location r, mol m^{-2} s^{-1}

k reaction rate constant; dimension depends on kinetic expression

k_{g} gas-phase mass-transfer coefficient for transfer from a gas to a liquid, m/s

$k_{\mathrm{g,A}}$ mass-transfer coefficient of component A in a gas, m/s

k_{l} liquid-phase mass-transfer coefficient for transfer from a gas to a liquid, m/s

k_{ls} liquid-phase mass-transfer coefficient for transfer from a liquid to a solid, m/s

$k_{\mathrm{l,A}}$ mass-transfer coefficient of component A in a liquid, m/s

$k_{n,m}$ reaction rate constant for bimolecular reactions with (n, m)-kinetics, m$^{3(n+m-1)}$ (mol A)$^{-(n-1)}$ (mol B)$^{-m}$, s^{-1}

k_{p} reaction rate constant based on pellet volume; dimension depends on kinetic expression

$k_{\mathrm{p,0}}$ pre-exponential factor for rate constant k_{p} (based on catalyst pellet volume)

$k_{\mathrm{p}}(T_{\mathrm{p}})$ reaction rate constant based on pellet volume for first-order kinetics at pellet temperature T_{p}, s^{-1}

k_{r} reaction rate constant; dimension depends on kinetic expression

k''_{r} surface reaction rate constant, m/s

k_{+} reaction rate constant of reaction to right-hand side; dimension depends on kinetic expression

k_{-} reaction rate constant of reaction to left-hand side; dimension depends on kinetic expression

k_{∞} reaction rate constant pre-exponential factor; reaction rate constant for infinite temperature; dimension depends on kinetic expression

K $= \frac{C_{\mathrm{P}}}{C_{\mathrm{A}}}, \frac{C_{\mathrm{P}}C_{\mathrm{Q}}}{C_{\mathrm{A}}C_{\mathrm{B}}}$; chemical equilibrium constant

K_{A} adsorption constant of component A, m^3/mol

K_{S} saturation constant in biochemical reactions, kg/m^3

$\mathrm{K}_0(u)$ zeroth-order modified Bessel function of the second kind:

$$K_0(u) = -\ln(u/2)\,\mathrm{I}_0(u) + \sum_{i=1}^{\infty}\left\{\mathrm{psi}(i+1)\left(\frac{u^i}{2^i i!}\right)^2\right\}$$

$\mathrm{K}_1(u)$ first-order modified Bessel function of the second kind:

$$\mathrm{K}_1(u) = \ln(u/2)\,\mathrm{I}_1(u) + -\frac{u}{2}\sum_{i=1}^{\infty} \times\left\{\frac{\mathrm{psi}(i+1) + \mathrm{psi}(i+2)}{2}\,\frac{(u/2)^{2i}}{i!\,(i+1)!}\right\}$$

L (1) length of plug-flow reactor, m
(2) parallelepiped length, m

Le $= \frac{a_{\mathrm{g}}}{\mathbb{D}_{\mathrm{A,g}}}$; gas Lewis number for component A

m (1) (apparent) reaction order of component B
(2) $= \frac{C_{\mathrm{A,i,l}}}{C_{\mathrm{A,i,g}}}$; dimensionless distribution coefficient or equilibrium constant of component A between gas and liquid phases

$m\,\mathrm{c}_k$ $\int_0^{\infty}(\theta-1)^k E(\theta)\,\partial\theta$; k-th central moment of dimensionless frequency distribution

$m\,\mathrm{o}_k$ $\int_0^{\infty}\theta^k E(\theta)\,\partial\theta$; k-th moment around origin of dimensionless frequency distribution

M_{A} molar mass of component A, kg/mol

M_{tot} total reaction mixture mass in closed system, kg

$M\,\mathrm{C}_k$ $\int_0^{\infty}(t-\bar{t})^k E(t)\,\partial t$; k-th central moment of frequency distribution, s^{k}

MO_k $\int_0^{\infty}t^k E(t)\,\partial t$; k-th moment around origin of frequency distribution, s^{k}

n (apparent) reaction order of component A

n_{A} number of moles of component A, mol

$n_{\mathrm{A},0}$ number of moles of component A for zero conversion, mol

$n_{\mathrm{T},0}$ number of moles of tracer injected in a pulse at $t = 0$, mol

psi (u) psi function; digamma function: $\mathrm{psi}\,(u) = -\gamma + \sum_{i=1}^{u-1} \frac{1}{i} \quad u \in \mathbb{Z}^+$

P_{A} partial pressure of component A, Pa

r radial coordinate, m

$r*$ radial coordinate in ring-shaped or cylindrical porous catalyst pellet, modified for pellet anisotropy, m

r_{c} core radius in shrinking core model, m

r_{p} (1) pellet radius in shrinking core model, m
(2) catalyst pellet radius, m

R ideal gas constant ($8.31434\,\mathrm{J\,mol^{-1}K^{-1}}$)

R_{A} chemical production rate of component A (if A is consumed, $R_{\mathrm{A}} < 0$; if A is produced, $R_{\mathrm{A}} > 0$), $\mathrm{mol\,m^{-3}\,s^{-1}}$

$|R_{\mathrm{A}}|$ chemical conversion rate of component A (positive if reaction proceeds in direction of arrow), $\mathrm{mol\,m^{-3}\,s^{-1}}$

$|R_{\mathrm{A}}|_{\mathrm{p}}$ conversion rate of component A based on catalyst pellet volume, $\mathrm{mol\,(m^3\,pellet)^{-1}\,s^{-1}}$

$|R_{\mathrm{A}}|_{\mathrm{P}}$ conversion rate of component A toward desired product P, $\mathrm{mol\,m^{-3}\,s^{-1}}$

$|\mathbb{R}_{\mathrm{A}}|_{\mathrm{X}}$ conversion rate of component A toward undesired byproduct X, $\mathrm{mol\,(m^{-3}\,s^{-1})}$

R_{i} inner radius of Raschig ring, m

R_{i}^* Raschig ring inner radius modified for pellet anisotropy, m

R_{u} outer radius of Raschig ring, m

R_{u}^* Raschig ring outer radius modified for pellet anisotropy, m

$|\mathbb{R}_{\mathrm{A}}|$ chemical reaction rate of component A; rate in absence of mass- or heat-transfer limitation, $\mathrm{mol\,m^{-3}\,s^{-1}}$

$|\overline{\mathbb{R}}_{\mathrm{A}}|$ average reaction rate for two nonmixed fluid microelements, $\mathrm{mol\,m^{-3}\,s^{-1}}$

$|\mathbb{R}''_{\mathrm{A}}|$ reaction rate based on pellet external surface area, $\mathrm{mol\,(m^2}$ external surface $\mathrm{area)^{-1}\,s^{-1}}$

$|\mathbb{R}_{\mathrm{A}}|_{\mathrm{mixed}}$ reaction rate for two mixed fluid microelements, $\mathrm{mol\,m^{-3}\,s^{-1}}$

$|\mathbb{R}_{\mathrm{A}}|_{\mathrm{p}}$ reaction rate based on pellet volume, $\mathrm{mol\,m^{-3}\,s^{-1}}$

$|\mathbb{R}''_{\mathrm{A}}|_{\mathrm{P}}$ rate of reaction yielding desired product P based on pellet external surface area, $\mathrm{mol\,(m^2}$ external surface $\mathrm{area)^{-1}\,s^{-1}}$

$|\mathbb{R}_{\mathrm{A}}|_{\mathrm{r}}$ chemical reaction rate based on reaction mixture or reactor volume, $\mathrm{mol\,m^{-3}\,s^{-1}}$

$|\mathbb{R}''_{\mathrm{A}}|_{\mathrm{X}}$ reaction rate of reaction yielding undesired byproduct X based on the pellet external surface area, $\mathrm{mol\,(m^2}$ external surface $\mathrm{area)^{-1}\,s^{-1}}$

$\sinh(u)$ hyperbolic sine function: $\sinh\,(u) = \frac{\mathrm{e}^u - \mathrm{e}^{-u}}{2}$

S cross-sectional area of tube or plug-flow reactor, $\mathrm{m^2}$

s fraction of stagnant fluid elements replaced per unit of time in Danckwerts penetration or surface renewal model, $\mathrm{s^{-1}}$

$\tanh(u)$ hyperbolic tangent function: $\tanh\,(u) = \frac{\mathrm{e}^{2u} - 1}{\mathrm{e}^{2u} + 1}$

T (1) reaction mixture temperature, K
(2) temperature inside a catalyst pellet, K

$\bar{t}$ reactor average residence time, s

$t_1\%$ time lapse needed for polymer chain radical concentration to reach 99 % of steady-state value, s

ΔT_{ad} $= \frac{\overline{C_{\mathrm{A,g}}}(-\Delta H_{\mathrm{r}})}{\varrho_{\mathrm{g}} C_{\mathrm{p,g}}}$; adiabatic temperature rise for monomolecular gas-phase reaction, K

$\overline{T_{\mathrm{g}}}$ temperature of gas bulk surrounding catalyst pellet, K

T_{i} temperature at external surface of catalyst pellet, K

$T_{\max}$ temperature at which the maximum rate is found for exothermic equilibrium reaction with fixed concentration in the reaction mixture, K

T_{p} catalyst pellet temperature for negligible intra particle temperature gradients, K

$T_{\mathrm{p,max}}$ $= \overline{T_{\mathrm{g}}} + \Delta T_{\mathrm{ad}}\, Le^{2/3}$; maximum pellet temperature for heterogeneously catalyzed gas-phase reaction, K

u superficial velocity; velocity based on empty tube cross-sectional area, m/s

u_{b} gas bubble rise velocity in liquid, m/s

u_x fluid velocity in x-direction, m/s

u_y fluid velocity in y-direction, m/s

u_z fluid velocity in z-direction, m/s

$\mathrm{U}(u)$ unit step function or Heaviside step function: $U(u) = \begin{cases} 0 & u < 0 \\ 1 & u \geq 0 \end{cases}$

V total reaction mixture volume, m^3

V_{p} pellet volume, m^3

W parallelepiped width, m

x coordinate perpendicular to interface through which mass transfer occurs, m

z axial coordinate in plug-flow reactor, m

α_{g} heat-transfer coefficient between catalyst pellet and surrounding gas, $\mathrm{W\,m^{-2}\,K^{-1}}$

γ $= \lim_{n\to\infty}\left(\sum_{i=1}^{n}\frac{1}{i} - \ln(n)\right)$ $= 0.5772156649$; Eulers constant

γ_{A} activity or fugacity coefficient of component A

γ_{B} $= v_B \frac{\mathbb{D}_{i,A}}{\mathbb{D}_{i,B}} \frac{C_{\mathrm{A,i}}}{C_{\mathrm{B,i}}}$; excess amount of component B for bimolecular reactions

γ_{p} pore tortuosity factor for porous pellet

δ film thickness in stagnant film model, m

δ_{A} film thickness for component A in stagnant film model, m

δ_{r} thickness of reaction zone in stagnant film with thickness $\delta > \delta_{\mathrm{r}}$, m

$\delta(u)$ Dirac delta function: $\delta(u) = \lim_{\varepsilon\to 0}\begin{cases} 0 & u < -\varepsilon, u > \varepsilon \\ \frac{1}{2\varepsilon} & -\varepsilon \leq u \leq \varepsilon \end{cases}$

Δ_{FK} error introduced on using Frank-Kamenetzki approximation

$\Delta_{\mathrm{FK,max}}$ maximum value of Δ_{FK} (i.e., for $C_{\mathrm{A}} = 0$ or low effectiveness factors)

ε (1) porosity of packed bed of catalyst pellets; volume fraction void (2) volume fraction of gas in gas-in-liquid dispersion

ε_{p} porosity of porous particle; fraction void volume

ζ_{A} relative degree of conversion of component A

$\zeta_{\mathrm{A,BR}}$ relative degree of conversion of component A in batch reactor

$\zeta_{\mathrm{A,CISTR}}$ relative degree of conversion of component A in CISTR

$\zeta_{\mathrm{A,CSSTR}}$ relative degree of conversion of component A in CSSTR

$\zeta_{\mathrm{A,equi}}$ relative degree of conversion of component A at equilibrium conditions

$\zeta_{\mathrm{A,PFR}}$ relative degree of conversion of component A in plug-flow reactor

ζ_{MO} relative degree of conversion of metal oxide in shrinking core model

$\zeta_{\mathrm{M,de}}$ maximum relative degree of conversion of monomer obtained for dead-end polymerization

η effectiveness factor; amount of key reactant converted in porous catalyst pellet, divided by amount that could be converted if no retardation by diffusion were to occur

$\eta^{\ominus}$ $= \frac{\overline{J_{\mathrm{A}}}aV}{kC_{\mathrm{A,i}}(1-\varepsilon)V}$; degree of reactor utilization

η_{P} $= \sigma_{\mathrm{P}}\,\zeta_{\mathrm{A}}$; yield of product P; ratio of amount of P formed to amount that could have been formed if all of key reactant A were converted solely to P

θ $= \frac{t}{\tau}$; dimensionless residence time in reactor

θ_g $= \frac{\overline{T_{\mathrm{g}}}}{\Delta T_{\mathrm{ad}}} Le^{2/3}$; dimensionless gas temperature

θ_p $= \frac{T_{\mathrm{p}}}{\Delta T_{\mathrm{ad}}} Le^{2/3}$; dimensionless pellet temperature

ι $= \frac{R_{\mathrm{i}}}{R_{\mathrm{u}}}$; dimensionless inner radius of Raschig ring

κ_{A} mole fraction of component A

$\overline{\kappa}_{\mathrm{A}}$ mole fraction of component A in bulk of fluid

$\kappa_{\mathrm{A,i}}$ mole fraction of component A at interface

λ $= \frac{H}{R_{\mathrm{u}}}$; dimensionless height of Raschig ring

λ_{g} gas thermal conductivity, $\mathrm{W\,m^{-1}\,K^{-1}}$

λ_{p} catalyst pellet thermal conductivity, $\mathrm{W\,m^{-1}\,K^{-1}}$

μ $= \frac{(-\Delta H_r)\mathbb{D}_{i,A}C_{A,i}}{\lambda_p T_i}$; measure of maximum relative temperature increase inside pellet

ν stoichiometric coefficient

ν' kg enzymes or cells per kg substrate in biochemical reactions

ν_B stoichiometric coefficient of component B

ξ_0 $= \frac{k_g A_p}{k_{p,0} V_p}$; mass-transfer rate to catalyst pellet over reaction rate at infinitely high temperature

$\xi_{0,bo}$ value of ξ_0 for which pellet blowout occurs

$\xi_{0,ra}$ value of ξ_0 for which pellet runaway occurs

$\xi(T_p)$ $= \frac{k_g A_p}{k_p(T_p) V_p}$; measure of mass-transfer rate to catalyst pellet divided by reaction rate

ϱ (1) density of reaction mixture, kg/m^3
(2) $= \frac{r_c}{r_p}$; dimensionless core radius in shrinking core model

ϱ_g gas density, kg/m^3

ϱ_0 density of reaction mixture for zero conversion, kg/m^3

σ_P selectivity toward product P; ratio of amount of P formed over amount that could have been formed if all of key reactant A had been converted to P

$\sigma_{P,Ha<0.2}$ selectivity toward desired product P for parallel reactions in slow reaction regime $Ha < 0.2$

$\sigma_{P,Ha>2}$ selectivity toward desired product P for parallel reactions in fast reaction regime $Ha > 2$

σ_t $= \sqrt{\sigma_t^2}$; standard deviation of frequency distribution, s

$\sigma^2{}_t$ $= MC_2$; variance of frequency distribution, s^2

$\sigma^2{}_\theta$ $= mc_2$; variance of dimensionless frequency distribution

τ (1) reactor holding time, s
(2) contact time between small stagnant fluid element and interface in Higbie penetration model, s

τ_D characteristic time for shrinking core in regime of slow diffusion through converted shell, s

τ_L $= \frac{(1-\varepsilon)V}{\varphi_{V1}}$; average residence time in liquid phase in bubble column, s

τ_M characteristic time for shrinking core in regime of slow external mass transfer, s

τ_R characteristic time for shrinking core in regime of slow reaction kinetics, s

φ $\equiv \frac{1}{\eta}$ for low η values thus high φ values; generalized Thiele modulus

φ_A $= \frac{V_p}{A_p}\sqrt{\frac{k_p}{\mathbb{D}_{i,A}}}$; Aris' shape-generalized Thiele modulus for first-order kinetics

φ_m mass flow rate, kg/s

φ_T $= r_p\sqrt{\frac{k_p}{\mathbb{D}_{i,A}}}$; simple Thiele modulus for first-order kinetics; not generalized for arbitrary catalyst geometries

φ_v volumetric flow rate, m^3/s

$\varphi_{v,0}$ volumetric flow rate of liquid feed to bubble column, m^3/s

$\varphi_{v,1}$ volumetric flow rate of liquid stream out of bubble column, m^3/s

χ $= \frac{E_a}{RT_i} \cdot \frac{(-\Delta H_r)\mathbb{D}_{i,A}C_{A,i}}{\lambda_p T_i}$; measure of maximum relative reaction rate increase inside pellet due to intra particle temperature gradients

ψ'' heat flux from or to catalyst pellet, W/m^2

ω_A mass fraction of component A

$\omega_{A,0}$ mass fraction of component A for zero conversion

1. Introduction

A rational approach to all problems relating to a physical or chemical change of matter must be based on elementary physical conservation laws. They have been handled systematically in, for example, [1] and [2]. For the treatment of chemical engineering phenomena, the laws of conservation of matter and energy are of primary importance; they are the basis of the discussions below. Flow phenomena, governed by the principle of conservation of momentum, naturally are equally important for chemical engineering calculations (→ Fluid Mechanics).

The second kind of information needed for a quantitative treatment of chemical engineering is concerned with rates. The rate at which a reaction proceeds may be determined not only by the

chemical kinetics of the reaction proper, but also by physical transport phenomena (→ Transport Phenomena).

The interaction between chemical kinetics and physical transport rates has received considerable attention during the past decades. DAMKÖHLER [3], and particularly FRANK-KAMENETZKI [4] have systematically developed this field. The latter author distinguished between *microkinetics* (i.e., chemical kinetics) and *macrokinetics* (i.e., physical rates). Many scientists (e.g., VAN KREVELEN [5], DANCKWERTS [6], and ASTARITA [7]) have stressed the importance of the scale of scrutiny, at which the phenomena in a reacting system are considered. In principle, three different scales must be taken into account:

1) The scale of a molecule, where, for example, molecular collisions and the molecule mean free path (diffusion) are studied
2) The scale of an eddy or dispersion in a heterogeneous system, where, for example, a catalyst particle or a gas bubble is taken as the basis for deriving the appropriate equations
3) The scale of a reactor as a whole, where small-scale phenomena must be integrated over the entire reactor and macroscopic mixing becomes important.

The discussion in the following chapters focuses on the scale described in item 2. If appropriate, references giving more extensive treatments are cited.

2. Fundamentals

2.1. Chemical Rates

For the application of material balance to chemical engineering problems, an expression must be available for the *chemical production rate*. The production rate of component A, R_A, is defined as the number of moles of A produced per unit time and volume. If A is consumed in a chemical reaction, R_A is negative; if A is produced, R_A is positive. The production rate in mass units is found by multiplying R_A by the molar mass M_A.

For convenience, the concept of the *chemical conversion rate* —R— is often used; it is always positive when a reaction proceeds in the direction of the arrow. The conversion rate is expressed in moles of key reactant consumed or produced per unit time and volume. When a reaction proceeds according to

$$\nu_A\,A + \nu_B\,B \rightarrow \nu_P\,P + \nu_Q\,Q$$

and A is chosen as key reactant:

$$|R| = -R_A = -R_B\frac{\nu_A}{\nu_B} = R_P\frac{\nu_A}{\nu_P} = R_Q\frac{\nu_A}{\nu_Q} \tag{2.1}$$

The coefficients ν_A, ν_B, ν_P, and ν_Q are called the *stoichiometric coefficients.*

In this text, the conversion rate is used in relevant equations to avoid difficulties in applying the correct sign for the reaction rate in material balances.

Note that the chemical conversion rate is not identical to the *chemical reaction rate*, which is denoted —$\mathbb{R}$—. The chemical reaction rate only reflects the chemical kinetics of the system, that is, the conversion rate measured under such conditions that it is not influenced by physical transport (diffusion and mass transfer) of reactants toward the reaction site or of product away from it. The reaction rate generally depends only on the composition of the reaction mixture, its temperature and pressure, and the properties of the catalyst. The conversion rate, in addition, can be influenced by the conditions of flow, mixing, and mass and heat transfer in the reaction system. For homogeneous reactions in which the reactants are well mixed on a molecular scale, and for heterogeneous reactions that proceed slowly with respect to potential physical transport, the conversion rate approximates the reaction rate. In constrast, for homogeneous reactions in poorly mixed fluids and for relatively rapid heterogeneous reactions, physical transport phenomena may reduce the conversion rate. Hence, in general, the conversion rate is lower than the reaction rate.

2.2. Relative Degree of Conversion

For a single reaction as given above, the mass fractions of the reactants, ω_A and ω_B, decrease and those of the products, ω_P and ω_Q, increase as the reaction proceeds from left to right. For a closed system (no material added or withdrawn),

$$\omega_{\mathrm{A}}+\omega_{\mathrm{B}}+\omega_{\mathrm{P}}+\omega_{\mathrm{Q}}=\text{ constant} \tag{2.2}$$

For such a system the *relative degree of conversion* ζ can be introduced, which is a measure of the extent to which the reaction has proceeded. It can be defined quite generally as the fraction of the amount of a reactant, fed prior to and during reaction, that has been converted. For a closed system, ζ can be expressed in terms of mass fractions:

$$\zeta_J=\frac{\omega_{J,0}-\omega_J}{\omega_{J,0}} \tag{2.3}$$

with J = A, B, respectively. Since, by definition, the total mass within a closed system M_{tot} is constant, the relative degree of conversion can also be expressed in terms of the number of moles:

$$\zeta_J=\frac{\frac{\omega_{J,0}M_{\mathrm{tot}}}{M_J}-\frac{\omega_J M_{\mathrm{tot}}}{M_J}}{\frac{\omega_{J,0}M_{\mathrm{tot}}}{M_J}}=\frac{n_{J,0}-n_J}{n_{J,0}} \tag{2.4}$$

with M_J being the molar mass of either A or B. If the total volume of the reaction mixture is not a function of the relative degree of conversion, the latter can be expressed relatively easily in terms of concentrations:

$$\zeta_J=\frac{\frac{n_{J,0}}{V}-\frac{n_J}{V}}{\frac{n_{J,0}}{V}}=\frac{C_{J,0}-C_J}{C_{J,0}} \tag{2.5}$$

with V the volume of the reaction mixture. If this volume changes during the reaction, Equation (2.5) yields

$$\zeta_J=\frac{C_{J,0}\frac{M_{\mathrm{tot}}}{\varrho_0}-C_J\frac{M_{\mathrm{tot}}}{\varrho}}{C_{J,0}\frac{M_{\mathrm{tot}}}{\varrho}}=\frac{\mathrm{C}_{\mathrm{J},0}-\frac{\varrho_0}{\varrho}C_J}{C_{J,0}} \tag{2.6}$$

with ϱ_0 being the density of the reaction mixture for zero conversion and ϱ the density for a conversion ζ.

The chemical reaction rate is usually dependent on the molar concentrations of the reactants and not on their mass fractions, because it depends on the change of collision of molecules. However, here the definition of ζ in terms of mass fractions is preferred, because it can readily be incorporated into mass balances. A definition in terms of moles or molar concentrations might invite the use of mole balances instead of mass balances. Since, contrary to conservation of mass, there is no such thing as conservation of moles (e.g., one molecule might split up in several molecules, or several might condense into one), the use of mole balances is strongly dissuaded.

More information concerning the definition of conversion can be found in WESTERTERP et al. [8].

2.3. Selectivity and Yield

In industrial chemical operations a reactant A or reactants A and B very often react to form not only desired products, but also undesirable ones. Therefore in chemical reactor technology the concepts of selectivity and yield are often used.

The *selectivity* σ_{P} is the ratio between the amount of desired product P obtained and the amount of key reactant A converted; both quantities are usually expressed such that σ_{P} ranges between 0 (no P formed) and 1 (all A converted to P). This definition leads to:

$$\sigma_{\mathrm{P}}=\frac{\left(\omega_{\mathrm{P}}-\omega_{\mathrm{P},0}\right)M_{\mathrm{A}}\nu_{\mathrm{A}}}{\left(\omega_{\mathrm{A},0}-\omega_{\mathrm{A}}\right)M_{\mathrm{P}}\nu_{\mathrm{P}}} \tag{2.7}$$

For constant density of the reaction mixture, this can be written as

$$\sigma_{\mathrm{P}}=\frac{\left(C_{\mathrm{P}}-C_{\mathrm{P},0}\right)\nu_{\mathrm{A}}}{\left(C_{\mathrm{A},0}-C_{\mathrm{A}}\right)\nu_{\mathrm{P}}} \tag{2.8}$$

The *yield* η_{P} is the ratio between the amount of desired product P obtained and the amount that could be obtained if all of key reactant A were converted to P with 100 % selectivity. Therefore, η_{P} can be calculated from

$$\eta_{\mathrm{P}}=\sigma_{\mathrm{P}}\zeta_{\mathrm{A}} \tag{2.9}$$

Like σ_{P}, the yield η_{P} usually varies between 0 and 1. It is high when both the selectivity and the relative degree of conversion are high; it is low when either of them is low.

If in the product separation section of the reactor, the key reactant A can be removed and recycled to the reactor, selectivity is the key factor in economical operation of the plant. If, however, A cannot be recycled, then yield is the key factor.

3. Microkinetics

3.1. Elementary Reactions

3.1.1. Fundamentals

Elementary reactions are individual reaction steps that are caused by collisions of molecules. The collision can occur in a more or less homogeneous reaction medium or at the reaction sites on a catalyst surface. Only three elementary kinetic processes exist: mono-, bi-, and trimolecular processes. Of these, trimolecular processes are rarely found, because the chance of three molecules colliding at the same time is very small.

Each elementary reaction consists of an activation of the reactants, followed by a transition state and decomposition of the latter into reaction products:

$$\mathrm{A}(+\mathrm{B})\left[\underset{\text{Deactivation}}{\overset{\text{Activation}}{\rightleftharpoons}}\left\{\begin{matrix}\text{Energized}\\ \text{molecule}\end{matrix}\right\}\longrightarrow\left\{\begin{matrix}\text{Transition}\\ \text{state}\\ \text{molecule}\end{matrix}\right\}\right]\longrightarrow\text{Products}$$

Energized and transition state molecules are unstable and as such cannot be isolated.

Figure 1. A) Temperature dependence of the reaction rate constant (note: as E_a/R ranges from 5000 to 35 000 K, in practice only the region $RT/E_a < 1$ is of interest); B) Enlargement of region $RT/E_a < 1$

3.1.2. Influence of Temperature

For elementary reactions, the influence of the temperature and composition of the reaction mixture can be represented separately. The influence of temperature is accounted for by the reaction rate constant k, referred to as a constant because it does not depend on the composition of the reaction mixture. The temperature dependence of k is as follows:

$$k = k_\infty \exp\left\{-\frac{E_a}{RT}\right\} \tag{3.1}$$

where E_a is the activation energy of the reaction.

Equation (3.1) is illustrated in Figure 1, where the reaction rate constant is plotted as a function of temperature (both quantities in dimensionless form). The term E_a/R is sometimes referred to as the *activation temperature*. For most reactions the activation energy lies in the range of 40 – 300 kJ/mol; hence the activation temperature E_a/R ranges from 5000 to 35 000 K. Therefore, industrially only the range $RT/E_a < 1$ is of interest: this region is shown enlarged in Figure 1 B. As can be seen from Figure 1 A, although at extreme temperatures k approaches k_∞, in practice it is several orders of magnitude lower.

The temperature increase required for doubling a reaction rate constant $\Delta T_{\mathrm{double}}$ as a function of the temperature of the reaction mixture and activation energy is given in Figure 2. The higher the activation energy, the more temperature sensitive are the reactions. To double the reaction rate at $T = 100\,°\mathrm{C}$, for example, a temperature increase of 3 °C ($E_a = 300$ kJ/mol) –20 °C ($E_a = 50$ kJ/mol) is required.

Figure 2. Temperature increase required to double the reaction rate constant ($\Delta T_{\mathrm{double}}$) for different values of the activation energy
a) $E_a = 50$ kJ/mol; b) $E_a = 150$ kJ/mol; c) $E_a = 300$ kJ/mol

3.1.3. Influence of Concentration

The influence of the composition of the reaction mixture on the chemical reaction rate is determined by the *chemical activity* (liquids) or *fugacity* (gases) of the reactants. These quantities can be expressed in relation to each other as

$$a_J = \frac{(\gamma_J P_J)}{RT} \tag{3.2}$$

where a_J is the chemical activity, γ_J the activity coefficient or fugacity coefficient, and P_J the partial pressure of component J. The product $\gamma_J P_J$ is called the fugacity. For ideal reaction mixtures, $\gamma_J = 1$ and the reaction rate is determined by the molar concentration or partial pressure of the reactants.

For elementary reactions and ideal reaction mixtures, the reaction rate is proportional to the concentration of each of the reactants, since the number of molecular collisions per unit time is proportional to the amount of molecules of each of the reactants. For example, for a bimolecular elementary reaction:

$$\mathrm{A} + \mathrm{B} \rightarrow \text{Products}$$

$$|\mathbb{R}| = k C_\mathrm{A} C_\mathrm{B} \tag{3.3}$$

If A is chosen as key reactant, $|\mathbb{R}|$ is expressed in moles of A converted per cubic meter of reaction mixture per second and k has the dimension of cubic meters of reaction mixture per mole of B per second. In this case, for a batch of V m^3 of reaction mixture,

$$|\mathbb{R}| = -\frac{1}{V}\frac{\partial n_\mathrm{A}}{\partial t} = -\frac{\nu_\mathrm{A}}{\nu_\mathrm{B}}\frac{1}{V}\frac{\partial n_\mathrm{B}}{\partial t} = k C_\mathrm{A} C_\mathrm{B} \tag{3.4}$$

or, if volume changes are negligible,

$$|\mathbb{R}| = -\frac{\partial C_\mathrm{A}}{\partial t} = -\frac{\nu_\mathrm{A}}{\nu_\mathrm{B}}\frac{\partial C_\mathrm{B}}{\partial t} = k C_\mathrm{A} C_\mathrm{B} \tag{3.5}$$

The notation given in Equation (3.5) is convenient for reactions carried out in liquids. For gases a more convenient notation is

$$|\mathbb{R}| = k' P_\mathrm{A} P_\mathrm{B} \tag{3.6}$$

with

$$k' = \frac{k}{R^2 T^2} \tag{3.7}$$

and

$$|\mathbb{R}| = -\frac{1}{RT}\frac{\partial P_\mathrm{A}}{\partial t} = -\frac{\nu_\mathrm{A}}{\nu_\mathrm{B}}\frac{1}{RT}\frac{\partial P_\mathrm{B}}{\partial t} = k' P_\mathrm{A} P_\mathrm{B} \tag{3.8}$$

For nonideal elementary reaction mixtures, the concentrations and partial pressures in the above equations must be replaced by the chemical activities and fugacities, respectively.

3.2. Chemical Equilibria

Section 3.1 assumes that the reactions described are irreversible. In practice, reactions are often reversible (i.e., the products can be converted into the reactants again):

$$\mathrm{A} + \mathrm{B} \underset{k_+}{\overset{k_-}{\rightleftharpoons}} \mathrm{P} + \mathrm{Q}$$

Figure 3. Dependence of reaction rate on temperature for equilibrium reactions
a) Endothermic reversible reaction; b) Exothermic reversible reaction

If both reactions are elementary and the reaction mixture is ideal, the chemical reaction rate is given by

$$|\mathbb{R}| = k_+ C_\mathrm{A} C_\mathrm{B} - k_- C_\mathrm{P} C_\mathrm{Q} \tag{3.9}$$

The activation energies of reaction E_+ and the reverse reaction E_- are related as

$$E_+ = E_- - (-\Delta H_\mathrm{r}) \tag{3.10}$$

where $(-\Delta H_\mathrm{r})$ is the reaction enthalpy [for exothermic reactions $(-\Delta H_\mathrm{r}) > 0$; for endothermic reactions $(-\Delta H_\mathrm{r}) < 0$].

Because of this, the temperature dependences of the reaction rate for exo- and endothermic equilibria are different (see Fig. 3). Initially, the rate increases with increasing temperature for both types of reaction. For *exothermic reactions* where $E_+ < E_-$, the value of k_- increases faster than the value of k_+. Above a certain temperature this can have the net result that —ℝ— in Equation (3.9) decreases with increasing temperature. Thus for exothermic reversible reactions, —ℝ— can, at constant reaction mixture composition, pass through a maximum as a function of temperature; it will become zero for the temperature at which the reaction mixture is at equilibrium (i.e., $k_+ C_A C_B = k_- C_P C_Q$) and negative beyond this value. For *endothermic reactions*, k_+ increases faster with increasing temperature than k_-; hence, —ℝ— continues to increase with increasing temperature, and the equilibrium shifts more and more to the right-hand side.

The temperature at which the maximum rate is found for exothermic reactions can be calculated from

$$T_{\max} = \frac{(-\Delta H_r)}{R}\left[\ln\left(\frac{C_P C_Q}{C_A C_B}\frac{k_- E_-}{k_+ E_+}\right)\right]^{-1} \tag{3.11}$$

Hence, this temperature depends on the composition of the reaction mixture. Therefore, for exothermic equilibrium reactions the temperature should be lowered as more reactant is converted, to keep the rate high. Thus this type of reaction is often carried out in multiple stages (e.g., multiple reactors or multiple zones within a reactor), each with its own temperature, adapted to the reaction mixture composition.

If the reaction rate becomes zero, chemical equilibrium is reached. For this situation the reaction mixture composition must fulfill the equilibrium condition

$$\frac{C_P C_Q}{C_A C_B} = K \tag{3.12}$$

where K is the equilibrium constant. Since —ℝ— = 0, from Equation (3.9), K can be calculated as

$$K = \frac{k_+}{k_-} \tag{3.13}$$

The equilibrium condition (Eq. 3.12) fixes the maximum obtainable relative degree of conversion, ζ_A, for a given initial reaction mixture composition and temperature. For example, if the reaction mixture exhibits ideal behavior and volume changes during the reaction are negligible,

$$C_A = C_{A,0} - C_{A,0}\zeta_A \tag{3.14}$$

$$C_B = C_{B,0} - C_{A,0}\zeta_A \tag{3.15}$$

$$C_P = C_{P,0} + C_{A,0}\zeta_A \tag{3.16}$$

$$C_Q = C_{Q,0} + C_{A,0}\zeta_A \tag{3.17}$$

Substitution in Equation (3.12) yields

$$\zeta_{A,\mathrm{equi}} = \frac{\alpha + \sqrt{\alpha^2 + 4\beta}}{2}$$
$$\alpha = \frac{1}{K-1}\left(\frac{C_{P,0}}{C_{A,0}} + \frac{C_{Q,0}}{C_{A,0}} + K\frac{C_{B,0}}{C_{A,0}} + K\right)$$
$$\beta = \frac{1}{K-1}\left(\frac{C_{P,0}C_{Q,0}}{C_{A,0}^2} - K\frac{C_{B,0}}{C_{A,0}}\right) \tag{3.18}$$

where $\zeta_{A,\mathrm{equi}}$ is the relative degree of conversion at equilibrium conditions. Similar equations can be derived for other equilibria.

3.3. Complex Reaction Schemes

3.3.1. Fundamentals

Only a few examples of chemical reaction rates determined by one elementary kinetic process are known. Conversion of reactants into products is mainly achieved via a scheme of elementary reactions. This scheme as a whole is generally referred to as the *mechanism* of a given overall conversion. A mechanism for the overall reaction A ⟶ P could be

$$\begin{array}{lll|c|c}
(1) & A \xrightarrow{k_1} 2\,X & & \times\frac{1}{2} & \\
(2) & A + X \xrightarrow{k_2} P + X & & \times\frac{1}{2} & \\
(3) & 2\,X \xrightarrow{k_3} P & & \times\frac{1}{2} & + \\
\hline
 & A \longrightarrow P & & &
\end{array}$$

The above mechanism is often found for the decomposition of polymerization initiators: A is the initiator (typically a peroxide or percarbonate); the intermediate X is a free radical that actually begins the growth of the polymer chain, and P is an inactive species. Reaction (1) is called

thermal decomposition, (2) induced decomposition, and (3) termination. The entire scheme is generally referred to as the induced initiator decomposition mechanism.

All of the above reactions are elementary; hence, if the reaction mixture is ideal and volume changes are negligible, the following rate equations are obtained:

$$\frac{\partial C_{\mathrm{A}}}{\partial t} = -k_1 C_{\mathrm{A}} - k_2 C_{\mathrm{A}} C_{\mathrm{X}} \tag{3.19}$$

$$\frac{\partial C_{\mathrm{X}}}{\partial t} = +2k_1 C_{\mathrm{A}} - k_3 C_{\mathrm{X}}^2 \tag{3.20}$$

To determine the concentration of A (and hence the relative degree of conversion) as a function of time, the above differential equations must be solved subject to the initial conditions:

$$t = 0 \rightarrow C_{\mathrm{A}} = C_{\mathrm{A},0} \quad \text{and} \quad C_{\mathrm{X}} = 0 \tag{3.21}$$

Thus, in general a simple kinetic expression is not obtained for complex reaction schemes, whereas for elementary reactions this is always the case. The above differential equations are not easily solved and do not yield a very clear picture.

To overcome these problems, the *pseudo-steady state assumption* can be made. This assumption postulates that the concentration of intermediates in a complex reaction scheme is pseudo-stationary compared to the transient behavior of the reactants and final products (i.e., the derivative of the concentration of intermediates with respect to time can be assumed to be zero). For the above reaction scheme, X is the intermediate and the pseudo-steady state assumption yields

$$\frac{\partial C_{\mathrm{X}}}{\partial t} = +2k_1 C_{\mathrm{A}} - k_3 C_{\mathrm{X}}^2 = 0$$

$$\Rightarrow C_{\mathrm{X}} = \sqrt{\frac{2k_1 C_{\mathrm{A}}}{k_3}} \tag{3.22}$$

Thus, a relatively simple expression is obtained for the intermediate concentration. Substituting the expression for C_{X} in the rate equation for A (Eq. 3.19), gives

$$\frac{\partial C_{\mathrm{A}}}{\partial t} = -k_1 C_{\mathrm{A}} - k_2 \sqrt{\frac{2k_1}{k_3}} C_{\mathrm{A}} \sqrt{C_{\mathrm{A}}} \tag{3.23}$$

This differential equation must be solved subject to

$$t = 0 \Rightarrow C_{\mathrm{A}} = C_{\mathrm{A},0} \tag{3.24}$$

which yields

$$C_{\mathrm{A}} = C_{\mathrm{A},0} \left[\left(1 + \sqrt{\frac{2k_2^2 C_{\mathrm{A},0}}{k_1 k_3}} \right) \exp\left(\frac{k_1 t}{2} \right) - \sqrt{\frac{2k_2^2 C_{\mathrm{A},0}}{k_1 k_3}} \right]^{-2} \tag{3.25}$$

For the pseudo-steady state assumption to be valid, we must have

$$\frac{\partial C_{\mathrm{X}}}{\partial t} << -2k_1 C_{\mathrm{A}} \tag{3.26}$$

or

$$\frac{-1}{2k_1 C_{\mathrm{A}}} \frac{\partial C_{\mathrm{X}}}{\partial t} << 1 \tag{3.27}$$

In analogy to Equation (3.22),

$$C_{\mathrm{X}} \approx \sqrt{\frac{2k_1 C_{\mathrm{A}}}{k_3}} \tag{3.28}$$

hence,

$$\frac{\partial C_{\mathrm{X}}}{\partial t} \approx \sqrt{\frac{k_1}{k_3 C_{\mathrm{A}}}} \frac{\partial C_{\mathrm{A}}}{\partial t} \tag{3.29}$$

Substituting Equation (3.23) gives

$$\frac{-1}{2k_1 C_{\mathrm{A}}} \frac{\partial C_{\mathrm{X}}}{\partial t} = \frac{1}{2k_3} \left(\sqrt{\frac{k_1 k_3}{C_{\mathrm{A}}}} + k_2 \sqrt{2} \right) << 1 \tag{3.30}$$

Thus, for this reaction scheme the pseudo-steady state assumption holds, e.g., if the termination rate is very fast (k_3 is very large). For an induced initiator decomposition (where X is a free radical), the termination reaction occurs between two free radicals. In general these reactions are very fast; hence the pseudo-steady state assumption is valid.

The rate equation for A (Eq. 3.23) was derived from the mechanism of the reaction. Most reactions are overall reactions; the exact mechanism behind them is often unknown, which means that kinetic data cannot be fitted to the exact rate equation. The chemical reaction rate can often be approximated by a so-called *power law equation*:

$$|\mathbb{R}| = k C_{\mathrm{A}}^n \tag{3.31}$$

If Equation (3.31) is used, the reaction is said to be of the order n with respect to A. The orders do not have to be whole numbers; thus, from Equation (3.23), for the discussed mechanism n can be 1 and 1.5, depending on the region covered by the kinetic data (temperature, concentration $C_{A,0}$). Also, if kinetic data are collected in a limited area where both right-hand terms in Equation (3.23) are important, n can take any value between 1 and 1.5.

For multimolecular overall reactions power laws can also be used; for example, for the bimolecular overall reaction

$$\nu_A\,A + \nu_B\,B \longrightarrow \text{Products}$$

the following equation can be written:

$$|\mathbb{R}| = k C_A^n C_B^m \tag{3.32}$$

The reaction is of order n with respect to A and of order m with respect to B; the total order of the reaction is $(n+m)$. Again, the orders n and m can be any numbers, not necessarily positive; negative values can also be found.

Figure 4. Arrhenius curve (i.e., ln — $\mathbb{R}$ — versus $1/T$) for monomolecular Langmuir kinetics

Hence, different sets of kinetic data, measured for different temperature or concentration ranges, yield different values for n and m. Therefore, if kinetic data or rate equations are obtained (e.g., from the literature), one should always ascertain that the region to which the kinetic data will be applied has indeed been explored experimentally. Extrapolation of kinetic data is generally impossible or very dangerous at least.

The principles discussed here can be used for any kinetic scheme in general. This will be illustrated further with some overall reactions often encountered in practice.

3.3.2. Polymerization Reactions

An ideal free-radical polymerization is studied as an example. The kinetic scheme of such a polymerization is given by

Initiation

$$\mathrm{I} \xrightarrow{k_{i,1}} 2\,\mathrm{R}^{\bullet}$$

$$\mathrm{R}^{\bullet} + \mathrm{M} \xrightarrow{k_{i,2}} \mathrm{P}_N^{\bullet}$$

Propagation

$$\mathrm{P}_N^{\bullet} + \mathrm{M} \xrightarrow{k_p} \mathrm{P}_{N+1}^{\bullet}$$

Termination

$$\mathrm{P}_M^{\bullet} + \mathrm{P}_N^{\bullet} \xrightarrow{k_t} \mathrm{P}_M + \mathrm{P}_N \quad \text{or} \quad \mathrm{P}_{M+N}$$

Transfer

$$\mathrm{P}_N^{\bullet} + \mathrm{T} \xrightarrow{k_s} \mathrm{P}_N + \mathrm{T}^{\bullet}$$

where I is the initiator, $\mathrm{R}^{\bullet}$ the free radical formed from the initiator; M a monomer unit; $\mathrm{P}_N^{\bullet}$ the growing, free-radical polymer chain; P_N the terminated, unreactive polymer chain; and T a chain-transfer agent (e.g., a polymer chain or monomer).

Induced initiator decomposition is not considered in the above scheme. To illustrate the pseudo-steady state assumption for the above scheme, the conversion – time curve is calculated and it will be investigated when the pseudo-steady state assumption holds.

3.3.2.1. Conversion – Time Curve

If the transfer reactions are neglected, the rate equations for the above scheme are

$$\frac{\partial C_I}{\partial t} = -k_{i,1} C_I \tag{3.33}$$

$$\frac{\partial C_M}{\partial t} = -k_{i,2} C_{R^{\cdot}} C_M - k_P C_{P^{\cdot}} C_M \tag{3.34}$$

$$\frac{\partial C_{R^{\cdot}}}{\partial t} = -k_{i,2} C_{R^{\cdot}} C_M + 2 f k_{i,1} C_I \tag{3.35}$$

$$\frac{\partial C_{\mathrm{P}^{\cdot}}}{\partial t} = -k_{\mathrm{t}} C_{\mathrm{P}^{\cdot}}^2 + k_{\mathrm{i},2} C_{\mathrm{R}^{\cdot}} C_{\mathrm{M}} \tag{3.36}$$

The parameter f is the initiator efficiency: if $f = 1$, all initiator decomposes to active radicals; for $f = 0$, no active radicals are formed from the initiator.

The aim is to arrive at a kinetic expression for the consumption of monomer, hence, the production of polymer. To achieve this, a pseudosteady state is assumed for the intermediate radicals $R^{\bullet}$ and $P^{\bullet}$. Pseudo-steady state for $R^{\bullet}$ yields

$$\frac{\partial C_{\mathrm{R}^{\cdot}}}{\partial t} = -k_{\mathrm{i},2} C_{\mathrm{R}^{\cdot}} C_{\mathrm{M}} + 2 f k_{\mathrm{i},1} C_{\mathrm{I}} = 0$$
$$\Rightarrow k_{\mathrm{i},2} C_{\mathrm{R}^{\cdot}} C_{\mathrm{M}} = 2 f k_{\mathrm{i},1} C_{\mathrm{I}} \tag{3.37}$$

Substitution of this equation into the rate equation for $P^{\bullet}$ (Eq. 3.36) gives

$$\frac{\partial C_{\mathrm{P}^{\cdot}}}{\partial t} = -k_{\mathrm{t}} C_{\mathrm{P}^{\cdot}}^2 + k_{\mathrm{i},2} C_{\mathrm{R}^{\cdot}} C_{\mathrm{M}}$$
$$= -k_{\mathrm{t}} C_{\mathrm{P}^{\cdot}}^2 + 2 f k_{\mathrm{i},1} C_{\mathrm{I}} \tag{3.38}$$

if a pseudo-steady state is assumed for $P^{\bullet}$,

$$\frac{\partial C_{\mathrm{P}^{\cdot}}}{\partial t} = -k_{\mathrm{t}} C_{\mathrm{P}^{\cdot}}^2 + 2 f k_{\mathrm{i},1} C_{\mathrm{I}} = 0$$
$$\Rightarrow C_{\mathrm{P}^{\cdot}} = \sqrt{\frac{2 f k_{\mathrm{i},1} C_{\mathrm{I}}}{k_{\mathrm{t}}}} \tag{3.39}$$

Substituting the terms $k_{\mathrm{i},2}\, C_{\mathrm{R}^{\bullet}}\, C_{\mathrm{M}}$ (Eq. 3.37) and $C_{\mathrm{P}^{\bullet}}$ (Eq. 3.39) in the rate equation for M (Eq. 3.34) yields

$$\frac{\partial C_{\mathrm{M}}}{\partial t} = -2 f k_{\mathrm{i},1} C_{\mathrm{I}} - k_{\mathrm{p}} \sqrt{\frac{2 f k_{\mathrm{i},1}}{k_{\mathrm{t}}}} \sqrt{C_{\mathrm{I}}} C_{\mathrm{M}} \tag{3.40}$$

If much less monomer is consumed in the initiation than in the propagation (as is the case, given the high molar masses of polymers) then

$$k_{i,2} C_{\mathrm{R}^{\cdot}} C_{\mathrm{M}} << k_{\mathrm{p}} C_{\mathrm{P}^{\cdot}} C_{\mathrm{M}}$$
$$\Rightarrow k_{\mathrm{i},1} C_{\mathrm{I}} << k_{\mathrm{p}} \sqrt{\frac{2 f k_{\mathrm{i},1}}{k_{\mathrm{t}}}} \sqrt{C_{\mathrm{I}}} C_{\mathrm{M}} \tag{3.41}$$

hence the rate equation for M becomes

$$\frac{\partial C_{\mathrm{M}}}{\partial t} = -k_{\mathrm{p}} \sqrt{\frac{2 f k_{\mathrm{i},1}}{k_{\mathrm{t}}}} \sqrt{C_{\mathrm{I}}} C_{\mathrm{M}} \tag{3.42}$$

In the literature, this equation is generally referred to as "ideal kinetics" for radical polymerization.

The initiator concentration as a function of time follows from Equation (3.33)

$$C_{\mathrm{I}} = C_{\mathrm{I},0} \exp\left(-k_{\mathrm{i},1} t\right) \tag{3.43}$$

Substitution in Equation (3.42) gives

$$\frac{\partial \zeta_{\mathrm{M}}}{\partial t} = \boldsymbol{k} \exp\left(-\frac{k_{\mathrm{i},1} t}{2}\right)(1 - \zeta_{\mathrm{M}}) \tag{3.44}$$

with ζ_{M} the relative degree of conversion of monomer:

$$\zeta_{\mathrm{M}} = \frac{C_{\mathrm{M},0} - C_{\mathrm{M}}}{C_{\mathrm{M},0}} \tag{3.45}$$

and $\boldsymbol{k}$ a constant defined according to

$$\boldsymbol{k} = k_{\mathrm{p}} \sqrt{\frac{2 f k_{\mathrm{i},1}}{k_{\mathrm{t}}}} \sqrt{C_{\mathrm{I},0}} \tag{3.46}$$

Equation (3.44) must be solved subject to the initial condition:

$$t = 0 \Rightarrow \zeta_{\mathrm{M}} = 0 \tag{3.47}$$

The solution to this equation is

$$\zeta_{\mathrm{M}} = 1 - \exp\left\{\frac{2\boldsymbol{k}}{k_{\mathrm{i},1}}\left[\exp\left(-\frac{k_{\mathrm{i},1} t}{2}\right) - 1\right]\right\} \tag{3.48}$$

This is a conversion time relation as it is typically found for an ideal free-radical polymerization (i.e., if macrokinetic phenomena are insignificant). In practice, in polymerizations these phenomena do become important for higher conversions (e.g., gel and glass effect) and therefore Equation (3.48) is of limited value only. More detailed discussions including macrokinetics specific for polymerizations are given in [9], [10]. From Equation (3.48), the maximum conversion is obtained for $t \to \infty$:

$$\zeta_{\mathrm{M,de}} = 1 - \exp\left[-2 k_{\mathrm{p}} \sqrt{\frac{2 f}{k_{\mathrm{t}} k_{\mathrm{i},1}}} \sqrt{C_{\mathrm{I},0}}\right] \tag{3.49}$$

This maximum conversion is less than unity because all the initiator is generally decomposed before all the monomer has had an opportunity to react. The fact that 100 % conversion cannot be reached due to initiator decomposition is commonly referred to as *dead-end polymerization*.

For $k_{\mathrm{i},1}\, t < 0.2$, Equation (3.48) can be approximated by

$$\zeta_{\mathrm{M}} = 1 - \exp\left(-\boldsymbol{k} t\right) \tag{3.50}$$

with $\boldsymbol{k}$ defined as in Equation (3.46). Hence, simple first-order kinetics are obtained; this is typical for the case in which thermal decomposition of the initiator can be neglected.

3.3.2.2. Radical Intermediates Concentration

To investigate the validity of the pseudo-steady state assumption the polymer chain radical concentration $C_{P\bullet}$ is calculated as a function of time. Initiator decomposition is assumed to be negligible, and for R· the pseudo-steady state assumption is taken as valid. Hence,

$$C_I = C_{I,0} \neq \text{function}\ (t) \tag{3.51}$$

and since Equation (3.37) holds,

$$k_{i,2} C_{R\cdot} C_M = 2 f k_{i,1} C_{I,0} \tag{3.52}$$

Substitution in the rate equation for P· (see Eq. 3.36) yields

$$\frac{6 C_{P\cdot}}{\partial t} = -k_t C_{P\cdot}^2 + 2 f k_{i,1} C_{I,0} \tag{3.53}$$

This differential equation must be solved subject to the initial condition

$$t = 0 \Rightarrow C_{P\cdot} = 0 \tag{3.54}$$

which gives the following solution:

$$C_{P\cdot} = \sqrt{\frac{2 f k_{i,1} C_{I,0}}{k_t}} \cdot \tanh\left(t\sqrt{2 f k_{i,1} k_t C_{I,0}}\right) \tag{3.55}$$

The steady-state concentration of polymer chain radicals, $C_{P\bullet,\text{steady}}$, is found for $t \to \infty$:

$$C_{P\cdot,\text{steady}} = \sqrt{\frac{2 f k_{i,1} C_{I,0}}{k_t}} \tag{3.56}$$

thus Equation (3.55) can be written as

$$\frac{C_{P\cdot}}{C_{P\cdot,\text{steady}}} = \tanh\left(t\sqrt{2 f k_{i,1} k_t C_{I,0}}\right) \tag{3.57}$$

Let $t_1\%$ be the time within which 99 % of the polymer chain radicals have reached the steady state:

$$\frac{C_{P\cdot}}{C_{P\cdot,\text{steady}}} = 0.99 \tag{3.58}$$

Then according to Equation (3.57),

$$t_1\% = \frac{\text{arctanh}\ (0.99)}{\sqrt{2 f k_{i,1} k_t C_{I,0}}} \frac{1.87}{\sqrt{f k_{i,1} k_t C_{I,0}}} \tag{3.59}$$

The values of $C_{P\bullet,\text{steady}}$ and $t_1\%$ are calculated below for the polymerization of methyl methacrylate with two specific initiators: bicyclohexylperoxybicarbonate (CPC) and 2,2′-azobisisobutyronitrile (ABI), respectively. The following data have been used:

$C_{i,0} = 5 \times 10^{-3}\text{mol/L}$
$k_{i,1}$ (CPC)
$= 1.37 \times 10^{16} \times \exp\left[-126 \times 10^3/(RT)\right] \text{s}^{-1}$
$k_{i,1}$ (ABI)
$= 1.58 \times 10^{15} \times \exp\left[-129 \times 10^3/(RT)\right] \text{s}^{-1}$
$k_t = 1.94 \times 10^{12} \times \exp\left[-29.3 \times 10^3/(RT)\right]$
$f = 0.5\,\text{L}\,\text{mol}^{-1}\text{s}^{-1}$

The values of $C_{P\bullet,\text{steady}}$ are

	40 °C	80 °C
CPC	5×10^{-8} mol/L	4×10^{-7} mol/L
ABI	1×10^{-8} mol/L	9×10^{-8} mol/L

and for $t_1\%$,

	40 °C	80 °C
CPC	2 s	0.07 s
ABI	11 s	0.4 s

The above time intervals show that the radical pseudo-steady state is reached in a matter of seconds or even fractions of a second. Thus, since residence times for polymerization are typically on the order of minutes to hours, pseudo-steady state can indeed be assumed.

3.3.3. Heterogeneous Catalytic Reactions

Heterogeneous catalytic reactions are reactions that take place on the surface of a solid catalyst. The following phenomena are significant in determining the microkinetics of these reactions:

1) Adsorption of the reactants
2) Reaction of the adsorbed reactants (e.g., with components in the gas phase or other adsorbed species)
3) Desorption of the products

The reaction itself can be monomolecular or bimolecular. Both situations are discussed below.

3.3.3.1. Monomolecular Reactions

A general mechanism for heterogeneously catalyzed monomolecular reactions is

$$A_{(gas)} \underset{k_a}{\overset{k_{-a}}{\rightleftharpoons}} A_{(ads)} \qquad \text{Adsorption}$$

$$\xrightarrow{k_r} P_{(ads)} + Q_{(gas)} \qquad \text{Reaction}$$

$$\xrightarrow{k_d} P_{(gas)} + Q_{(gas)} \qquad \text{Desorption}$$

A kinetic expression for the above reaction can be obtained by assuming a pseudo-steady state for the adsorbed species $A_{(ads)}$ and $P_{(ads)}$. A measure of the concentrations of these species is the *degree of occupation*, θ_A and θ_P, respectively: θ_A and θ_P are defined such that they range from zero (no active surface area covered at all) to unity (all active surface area covered). Applying the pseudo-steady state assumption to the rate equations of the adsorbed species gives

$$\frac{\partial \theta_A}{\partial t} \sim k_a P_A (1-\theta_A-\theta_P) - k_{-a}\theta_A - k_r\theta_A = 0 \quad (3.60)$$

$$\frac{\partial \theta_P}{\partial t} \sim k_r\theta_A - k_d\theta_P = 0 \quad (3.61)$$

The overall chemical reaction rate is obtained from

$$|\mathbb{R}| = -\frac{\partial C_A}{\partial t} = \frac{\partial C_P}{\partial t} = k_d\theta_P \quad (3.62)$$

Combining Equations (3.60), (3.61), and (3.62), and substituting expressions for θ_A and θ_P, gives

$$|\mathbb{R}| = \frac{k_r \frac{k_a}{k_{-a}} P_A}{\left(1+\frac{k_r}{k_{-a}}\right) + \left(1+\frac{k_r}{k_d}\right)\frac{k_a}{k_{-a}} P_A} \quad (3.63)$$

which is generally written as

$$|\mathbb{R}| = k\frac{K_A P_A}{1+K_A P_A} \quad (3.64)$$

k and K_A are lumped parameters, which can be obtained by comparing Equations (3.63) and (3.64). The above expression is referred to as *Langmuir kinetics*. For low partial pressures of A the rate is first order in A; for high partial pressures it becomes zero order because $K_A P_A >> 1$.

If the adsorption and desorption rates in the above scheme are much higher than the rate of the surface reaction (i.e., k_a, k_{-a}, $k_d >> k_r$), Equation (3.63) can be approximated by

$$|\mathbb{R}| \approx k_r \frac{\frac{k_a}{k_{-a}} P_A}{1+\frac{k_a}{k_{-a}} P_A} = k_r \frac{b_A P_A}{1+b_A P_A} \quad (3.65)$$

with

$$b_A = \frac{k_a}{k_{-a}} = b_{A,\infty} \exp\left[\frac{(-\Delta H_{ads})}{RT}\right] \quad (3.66)$$

and $(-\Delta H_{ads})$ the adsorption enthalpy of A on the active catalyst surface. Since the adsorption of a given component is an exothermic process, $(-\Delta H_{ads})$ is positive. An Arrhenius plot (i.e., the logarithm of the reaction rate versus the reciprocal absolute temperature) for this situation is given in Figure 4. For low temperatures, b_A is large (θ_A close to unity) and the rate is zero order:

$$|\mathbb{R}| \approx k_r = k_{r,\infty} \exp\left(-\frac{E_a}{RT}\right) \quad (3.67)$$

Hence, for low temperatures the energy of activation equals E_a and is relatively large. As the temperature increases, the value of b_A (or θ_A) decreases and the reaction becomes first order:

$$|\mathbb{R}| \approx k_r b_A P_A = k_{r,\infty} b_{A,\infty} \exp\left[-\frac{E_a - (-\Delta H_{ads})}{RT}\right] P_A \quad (3.68)$$

So, in this regime, a smaller, apparent activation energy is found that is equal to $E_a - (-\Delta H_{ads})$.

3.3.3.2. Bimolecular Reactions

For bimolecular, heterogeneously catalyzed reactions, two mechanisms can be distinguished:

1) *Eley–Rideal Mechanism*. One of the reactants is adsorbed on the catalyst surface, the other reacts from the gas phase :

$$A_{(gas)} \underset{k_a}{\overset{k_{-a}}{\rightleftharpoons}} A_{(ads)}$$

$$A_{(ads)} + B_{(gas)} \underset{k_r}{\overset{k_{-r}}{\rightleftharpoons}} P_{(ads)}$$

$$P_{(ads)} \xrightarrow{k_d} P_{(gas)}$$

2) *Langmuir – Hinshelwood Mechanism.* Both reactants are adsorbed and react as adsorbed species :

$$A_{(gas)} \underset{k_a}{\overset{k_{-a}}{\rightleftharpoons}} A_{(ads)}$$

$$B_{(gas)} \underset{k_b}{\overset{k_{-b}}{\rightleftharpoons}} B_{(ads)}$$

$$A_{(ads)} + B_{(ads)} \underset{k_r}{\overset{k_{-r}}{\rightleftharpoons}} P_{(ads)}$$

$$P_{(ads)} \xrightarrow{k_d} P_{(gas)}$$

Both mechanisms are illustrated in Figure 5. A description of these mechanisms is given below.

The pseudo-steady state assumption for the adsorbed species in the *Eley – Rideal mechanism* yields

$$\frac{\partial \theta_A}{\partial t} \sim k_a P_A (1-\theta_A-\theta_P) - k_{-a}\theta_A - k_r P_B \theta_A + k_{-r}\theta_P = 0 \tag{3.69}$$

$$\frac{\partial \theta_P}{\partial t} \sim k_r P_B \theta_A - k_{-r}\theta_P - k_d \theta_P = 0 \tag{3.70}$$

The overall chemical reaction rate is now obtained from

$$|\mathbb{R}| = k_r P_B \theta_A - k_{-r}\theta_P \tag{3.71}$$

Combining the above equations gives

$$|\mathbb{R}| = \frac{k_r \frac{k_a}{k_{-a}} P_A P_B}{1+\frac{k_{-r}}{k_d}+\frac{k_a}{k_{-a}}\left(1+\frac{k_{-r}}{k_d}\right)P_A+\frac{k_r}{k_{-a}}P_B+\frac{k_a k_r}{k_{-a}k_d}P_A P_B} \tag{3.72}$$

From this formula, several limiting regimes can again be obtained: for example, if the adsorption equilibrium rates are still much higher than the rate of the surface reaction (i.e., k_a, k_{-a}, $k_d >> k_r$, k_{-r}), Equation (3.71) can be approximated by

$$|\mathbb{R}| = k_r \frac{b_A P_A}{1+b_A P_A} P_B \tag{3.73}$$

with b_A again

$$b_A = \frac{k_a}{k_{-a}} \tag{3.74}$$

From the *Langmuir – Hinshelwood mechanism* a formula similar to Equation (3.72) can be derived. This formula, however, is rather complex and bulky. Therefore, here only the limit is discussed, where adsorption and desorption rates are again much higher than the rate of the surface reaction (i.e., k_a, k_{-a}, k_b, k_{-b}, $k_d >> k_r$, k_{-r}). For this situation,

$$|\mathbb{R}| = k_r \frac{b_A b_B P_A P_B}{(1+b_A P_A + b_B P_B)^2} \tag{3.75}$$

with b_A according to Equation (3.74) and

$$b_B = \frac{k_b}{k_{-b}} \tag{3.76}$$

If the partial pressure of one of the components (e.g., A) is increased, the reaction rate does not necessarily have to increase: for a certain value of P_A the maximum rate is obtained; above this pressure the rate decreases with increasing P_A. The explanation is that for high P_A values, adsorption of A is so strong that it hampers adsorption of reactant B and thus retards the surface reaction. Consequently, negative reaction orders can also be found: for both components the reaction order is between -1 and 1.

Examples of systems exhibiting Langmuir – Hinshelwood-type behavior are the oxidation of CO on platinum and palladium (order for CO is -1, and for O_2 between 0 and 1); the hydrogenation of C_2H_4 on nickel (order for C_2H_4 is between -1 and 0, and for H_2 between 0 and 1); and the reaction $N_2O + H_2 \longrightarrow N_2 + H_2O$ on platinum and gold (order for N_2O is between 0 and 1, and for H_2 -1).

3.3.4. Biochemical Reactions

Biochemical reactions typically occur according to the following scheme:

$$A \xrightarrow{k_P} P \begin{cases} \xrightarrow{k_X} X \\ \rightarrow Q \end{cases}$$

The stoichiometric coefficients are considered below.

A is called the substrate and P represents the enzymes or living cells. The substrate is consumed, the cells grow, and a desired product Q is formed. However, the enzymes or cells also decompose or die according to the reaction

Figure 5. Elementary steps involved in bimolecular, heterogeneously catalyzed reactions
A) According to Eley – Rideal; B) According to Langmuir – Hinshelwood

P $\longrightarrow$ X. In wastewater treatment, A represents the water contaminants and Q represents CO_2 and H_2O. In ethanol production, A represents the sugar, P the yeast cells, X the dead cells, and Q the ethanol, CO_2, and H_2O.

In biochemical reactions where a living microorganism P (a type of bacteria or cell) is fed with a substrate A, the cell grows as a consequence, and the number of cells increases. A possible mechanism to describe this phenomenon was first postulated by MICHAELIS and MENTEN [11]. Based on their mechanism, a kinetic equation was proposed by MONOD [12]. Here, this kinetic equation is given without going into details of the exact mechanism. If the dying or decomposition rate $k_X\, C_P$ is not considered, the expression is

$$|\mathbb{R}_P| = \frac{\partial C_P}{\partial t} = k_P \frac{C_A}{K_S + C_A} C_P \tag{3.77}$$

Notice the resemblance to Eley – Rideal kinetics in the case where the adsorption and desorption rates are much higher than the rate of the surface reaction (see Eq. 3.73).

In Equation (3.77), K_S is often called the *saturation constant*: this is the concentration C_A at which — $\mathbb{R}_P$ — reaches half of its maximum value for a given value of C_P. The cell growth rate varies between zero and first order with respect to substrate concentration, so two extreme kinetic regimes can be distinguished:

1) The *uninhibited growth phase* ($C_A >> K_S$), where more than sufficient feed is available for the cells to reproduce in accordance with the number of cells available or — $\mathbb{R}_P$ — $= k_P\, C_P$
2) The *feed-limited growth phase* ($C_A << K_S$), with — $\mathbb{R}_P$ — $= k_P\, C_P\, (C_A/K_S)$, where insufficient feed is available and the cells will grow in accordance with the feed and the number of cells available

Concentrations and K_S are usually expressed in mass per unit volume (kg/m^3) because of the difficulty of determining molar concentrations in biotechnology. The dimension of k_P is per unit time (s^{-1}).

The substrate consumption rate equals

$$|\mathbb{R}| = -\frac{\partial C_A}{\partial t} = \frac{k_P}{\nu'} \frac{C_A}{K_A + C_A} C_P \tag{3.78}$$

In this equation, ν' is a kind of stoichiometric coefficient, which is often called the *yield factor*. It is expressed as mass of cells formed per mass of substrate consumed (kg/kg).

Monod kinetics are *autocatalytic*. The cells P have to be present to start reproduction of the cells and, as long as there is sufficient substrate available, the more cells have already been produced, the faster they will reproduce, i.e., the higher — $\mathbb{R}_P$ —.

Many extensions of Monod kinetics have been proposed in the past. A survey is given in [13]. One simple extension is, of course, inclusion of the fact that part of the microorganisms die with a rate of $k_X\, C_P$ as discussed above. Then,

$$|\mathbb{R}_P| = \frac{\partial C_P}{\partial t} = k_P \frac{C_A}{K_S + C_A} C_P - k_X C_P \tag{3.79}$$

The rate expressions for biochemical reactions are very sensitive to temperature and to the pH of the reaction mixture, as illustrated in Figure 6. An optimum temperature exists at which microorganisms grow most comfortably; below this temperature the microorganisms are relatively inactive, and above this temperature degradation sets in rapidly. Many microorganisms are optimal at $pH_{opt} = 6.5 \pm 1$, the exact value of the pH depending on the type of microorganism. Typically at $pH_{opt} \pm (1.0 - 1.5)$,

the activity has already been reduced to half of its value at pH_{opt}.

Figure 6. Effect of temperature (A) and pH (B) on cell growth in biochemical reactions

4. Macrokinetics: Single-Phase Systems

4.1. Introduction

A significant macrokinetic phenomenon for single-phase systems is the extent of *micromixing* (i.e., the extent to which the fluid travels as lumps of molecules). To visualize the difference between a micromixed and nonmicromixed fluid, one could think of a viscous fluid partially mixed with a colored fluid with the same properties. On a macroscale the fluid may seem of a uniform color, but viewed through a microscope, streaks and isolated domains of more or less intensive color might be seen (Fig. 7). If such nonhomogeneous domains exist, the fluid is called a (partially) *segregated fluid* or *macrofluid*. An emulsion of oil in water, where the oil is segregated in clearly distinguishable domains (oil droplets), is an extreme example of a macrofluid. Only if the mixture remains uniform on an ever-decreasing scale can it be considered a *microfluid*.

Based on the work of Kolmogoroff [14], [15], Batchelor [16], Corrsin [17], and Rosenweig [18], a characteristic dimension of the agglomerates in the fluid can be estimated as a function of hydrodynamic factors (e.g., stirrer power input) and fluid properties (e.g., viscosity).

The size of these agglomerates alone, however, is not sufficient to discriminate between a macro- or a microfluid. Generally, the effect of the state of segregation can be judged only in relation to conversion rate and reactor residence time: the same fluid at the same flow conditions may behave like both a macro- and a microfluid, depending on rate and residence time. If the reaction rate is low and thus reaction time is long compared to residence time or to the life span of an agglomerate in the reactor, the overall conversion can be calculated by assuming the fluid to behave like a microfluid. However, in the case of an extremely short reaction time or fast reaction and a short residence time, the life span of the agglomerate may be long in comparison, and the conversion can be found by assuming that the fluid behaves effectively as a macrofluid.

Therefore, to be able to assess the impact of micromixing, *macromixing* must be discussed. Macromixing means mixing on the scale of the whole reactor, as opposed to micromixing, which applies to the microscopic scale of the agglomerates (e.g., oil droplets). In Chapter 1, three scales are defined on which to consider the phenomena in a reacting system: (1) the scale of the molecules (microkinetics); (2) the scale of an eddy or dispersion, e.g., droplet, bubble, particle (macrokinetics); and (3) the scale of the

Figure 7. A) Illustration of a macrofluid (sometimes called partially segregated fluid); B) Illustration of a microfluid

reactor. Macromixing belongs to the third scale, whereas micromixing belongs to the second.

Since, in this chapter, the macrokinetic scale is dealt with, strictly speaking macromixing should not be considered here because it does not belong to this scale. However, as outlined above, to be able to understand the impact of micromixing one must have some knowledge of macromixing. Therefore, macromixing and the sequence of mixing are discussed below. For further references, see [2], [8], [19].

4.2. Macromixing

4.2.1. Residence-Time Distribution (RTD)

Because in many cases the hydrodynamic behavior of fluid flow through a real reactor cannot be predicted or even described, a need often exists for a simplified model with experimental data on fluid flow. A very powerful concept is the residence-time distribution, which is essentially a statistical approach for description of fluid flow. A typical element of the fluid is considered as it enters the reactor. The probability of leaving the reactor after a certain residence time there is expressed as a *residence-time distribution* (RTD). The idea was first discussed by DANCKWERTS [20].

The many elements of a fluid entering the reactor at a certain moment $t = 0$ generally do not reside in the reactor for exactly the same period; rather, there is a distribution of residence times. This can be represented in terms of the *frequency distribution*, usually called the E diagram in RTD descriptions (see Fig. 8). The shaded area $E(t)\,\partial t$ represents the fraction of fluid elements that enter the reactor at $t = 0$ and leave between t and $t + \partial t$. Stated otherwise, it represents the chance of a fluid element having a residence time between t and $t + \partial t$. The E diagram thus defined has an area of unity below the curve because all fluid elements have a residence time between 0 and ∞, and hence the fraction of fluid elements with a residence time between 0 and ∞ equals unity. Thus,

$$\int_0^\infty E(t)\,\partial t = 1 \tag{4.1}$$

Figure 8. The residence-time distribution (RTD) given by an $E(t)$ diagram
The shaded area $E(t)\,\partial t$ represents the chance of a fluid element having a residence time between t and $t + \partial t$.

To characterize the residence-time distribution in terms of statistical parameters such as the average residence time, spread in residence time, or skewness of distribution, moments are used. The k th moment MO_k around the origin is defined as

$$\mathrm{MO}_k = \int_0^\infty t^k E(t)\,\partial t \tag{4.2}$$

Notice that the zeroth moment around the origin per definition must equal unity (see Eq. 4.1):

$$\mathrm{MO}_0 = \int_0^\infty E(t)\,\partial t = 1 \tag{4.3}$$

The first moment around the origin equals the average residence time $\bar{t}$:

$$\bar{t} = \mathrm{MO}_1 = \int_0^\infty tE(t)\,\partial t \tag{4.4}$$

The k-th central moment MC_k is defined as

$$\mathrm{MC}_k = \int_0^\infty (t-\bar{t})^k\, E(t)\,\partial t \tag{4.5}$$

The first central moment always equals zero, since by definition

$$\mathrm{MC}_1 = \int_0^\infty (t-\bar{t})\, E(t)\,\partial t$$
$$= \int_0^\infty tE(t)\,\partial t - \bar{t}\int_0^\infty E(t)\,\partial t = 0 \tag{4.6}$$

The second central moment is called the variance $\sigma^2{}_t$:

$$\sigma_t^2 = \mathrm{MC}_2 = \int_0^\infty (t-\bar{t})^2\, E(t)\,\partial t$$
$$= \mathrm{MO}_2 - \mathrm{MO}_1^2 \tag{4.7}$$

Figure 9. Cumulative RTD function or F diagram $F(t)$ represents the fraction of fluid elements in the vessel exit stream with a residence time shorter than $t \cdot$ s

The spread in the residence time is characterized by the standard deviation σ_t, defined as the square root of the variance:

$$\sigma_t = \sqrt{\sigma_t^2} \tag{4.8}$$

Higher moments, which are used in quantities such as skewness and peakedness of the RTD function, are employed less frequently.

The E diagram is often also presented, by using a reduced time, as $E(\theta)$ versus θ:

$$\theta = \frac{t}{\tau} \tag{4.9}$$

Here τ is the holding time, which for a fluid of constant density can be obtained from

$$\tau = \frac{V}{\varphi_v} \tag{4.10}$$

in which V is the volume accessible for the fluid (e.g., volume of the reaction mixture inside the reactor) and φ_v the fluid volumetric flow rate (m^3/s). The average residence time $\bar{t}$ can differ from the holding time τ, for example, if the fluid is adsorbed on a catalyst, reactor walls, or internals. In the case of adsorption, the average residence time is longer than the holding time. Below, adsorption phenomena are assumed to not play a significant role, in which case

$$\tau = \bar{t} \tag{4.11}$$

For the parameters t and θ, the respective E diagrams are related by

$$E(t) = \frac{1}{\tau}E(t/\tau) = \frac{1}{\tau}E(\theta) \tag{4.12}$$

As in Equation (4.2) for $E(\theta)$, moments around the origin are defined as

$$\mathrm{mo}_k = \int_0^\infty \theta^k E(\theta)\,\partial\theta \tag{4.13}$$

Since "the average dimensionless residence time" equals unity, $\mathrm{mo}_1 = 1$:

$$\mathrm{mo}_1 = \int_0^\infty \theta E(\theta)\,\partial\theta = \int_0^\infty tE\left(\frac{t}{\tau}\right)\partial\frac{t}{\tau}$$
$$= \frac{1}{\tau}\int_0^\infty tE(t)\,\partial t = 1 \tag{4.14}$$

Figure 10. Examples of short-cutting (A) and dead zones (B) with their corresponding appearances in the $E(t)$ diagram

Figure 11. Idealized tracer injection pulse: the δ function or Dirac delta function (right) as an extreme case of a block function (left)

As above, the k-th central moment mc_k is:

$$\mathrm{mc}_k = \int_0^\infty (\theta - 1)^k \, E(\theta) \, \partial\theta \tag{4.15}$$

and the variance is

$$\sigma_\theta^2 = \mathrm{mc}_2 = \int_0^\infty (\theta - 1)^2 \, E(\theta) \, \partial\theta$$
$$= \mathrm{mo}_2 - \mathrm{mo}_1^2 \tag{4.16}$$

A complementary presentation of the residence-time distribution can be made by a cumulative function called the $F(t)$ diagram (see Fig. 9). Here the fraction $F(t)$ of the elements with a residence time shorter than t is plotted. The E and F diagrams are related by

$$F(t) = \int_0^t E(u) \, \partial u \tag{4.17}$$

The functions E and F are equivalent, but some properties are more easily demonstrated with an E diagram, so they are used more frequently.

Experimentally observed RTD functions can be used for identification of reactor malfunctioning. Two cases are illustrated in Fig-

ure 10. Short-cutting is visible in the front part of the E diagram, because a relatively large fraction of the fluid has a very short residence time. If, on the other hand, dead zones are present, a relatively large fraction of the fluid has a very long residence time, which is indicated by an excessively long tail on the E curve. In extreme cases the tail may not be detectable because of very slow renewal of the fluid in the dead zone by the active part of the fluid. In that case the average residence time observed from the E diagram is shorter than $\tau = V/\varphi_v$. If, in contrast, the average residence time observed from the E diagram is much longer than τ, then adsorption phenomena as discussed above must be taken into account.

The general procedure for an RTD determination is that fluid elements flowing into the reactor or the measuring section are marked and detected at the outlet. This marking is performed by changing some property with time. Mostly the concentration of a tracer substance is varied. Such a tracer substance must be easily detectable in low concentration (e.g., via changes in electrical or thermal conductivity, light adsorption, or radioactive radiation). Furthermore the tracer must not have a significant effect on bulk fluid properties (e.g., density, viscosity). Two types of incoming tracer signals are frequently used:

1) A sharp pulse, where at $t = 0$ a certain amount of tracer is injected into the inlet stream in the shortest possible time. Mathematically this is represented by the *Dirac delta function* $\delta(t)$, illustrated in Figure 11 where the delta function is depicted as an extreme case of a block function. An advantage of δ-pulse injection is that after normalization the $E(t)$ diagram is obtained directly as a response (albeit, this holds only if the reactor is a closed system [8]).
2) A step function where at $t = 0$ the incoming concentration is changed from one steady value (usually zero) to another. Mathematically this is represented by the *unit step function* $\mathrm{U}(t)$, also called the *Heaviside step function* (see Fig. 12). After normalization the direct response of the step function is the $F(t)$ diagram (again, for closed systems only).

Figure 12. Idealized tracer injection function: unit step function $\mathrm{U}(t)$, also called the Heaviside step function

Other types of incoming tracer signals can also be used (a steady sinusoidal variation or even arbitrary signals) and are discussed in [8].

The RTDs of some model reactors are discussed in the following sections.

4.2.2. Batch Reactor (BR)

Basically a batch reactor is a vessel in which a reaction is carried out, with no material being supplied to or withdrawn from it during the reaction. Hence a batch reactor does not have a residence-time distribution: all elements in the reactor have the same residence times. If an ideal reaction mixture and negligible volume changes are assumed, for a momomolecular reaction the composition inside the batch reactor as a function of time follows from

$$\frac{\partial C_\mathrm{A}}{\partial t} = -|\mathbb{R}_\mathrm{A}| \tag{4.18}$$

where A is the reactant. By introducing the relative degree of conversion ζ_A as

$$\zeta_\mathrm{A} = \frac{C_\mathrm{A}|_{t=0} - C_\mathrm{A}|_t}{C_\mathrm{A}|_{t=0}} \tag{4.19}$$

Equation (4.18) can be written as

$$t = C_\mathrm{A}|_{t=0} \int_0^{\zeta_\mathrm{A}} \frac{\partial \zeta_\mathrm{A}}{|\mathbb{R}_\mathrm{A}|} \tag{4.20}$$

For example, for a first-order reaction where

$$|\mathbb{R}_\mathrm{A}| = kC_\mathrm{A}|_{t=0}(1-\zeta_\mathrm{A}) \tag{4.21}$$

Equation (4.20) yields

$$\zeta_\mathrm{A} = 1 - \mathrm{e}^{-kt} \tag{4.22}$$

For reactions of n th order, similar expressions can be found.

4.2.3. Plug-Flow Reactor (PFR)

In a plug-flow reactor the reaction mixture flows like a plug through a tube; the linear velocity u is the same at every point in a cross section perpendicular to the direction of flow and equals

$$u = \frac{\varphi_v}{S} \tag{4.23}$$

with S the cross-sectional area (m^2) and φ_v the volumetric flow rate of the reaction mixture (m^3/s).

The composition of the reaction mixture depends on the distance z from the inlet point (see Fig. 13). To calculate concentration profiles across the length, a material balance must be applied to a differential volumetric section $S\,\partial z$. applied to a differential volumetric section $S\,\partial z$. For a reactant A this yields (if volume changes during the reaction are negligible)

$$\varphi_v\,\partial C_A = -|\mathbb{R}_A| S\,\partial z \tag{4.24}$$

Introducing the relative degree of conversion ζ_A as

$$\zeta_A = \frac{C_A|_{z=0} - C_A|_z}{C_A|_{z=0}} \tag{4.25}$$

yields

$$\partial\zeta_A = \frac{|\mathbb{R}_A| S}{\varphi_v C_A|_{z=0}}\,\partial z \tag{4.26}$$

In this equation, only — $\mathbb{R}_A$ — depends on ζ_A. The reactor volume $V = SL$ needed to reach a relative degree of conversion equal to $\zeta_{A,L}$ can be calculated from

$$V = \varphi_v C_A|_{z=0} \int_0^{\zeta_{A,L}} \frac{\partial\zeta_A}{|\mathbb{R}_A|} \tag{4.27}$$

By introducing the reactor holding time (or since no adsorption is assumed, the reactor residence time) $\tau = V/\varphi_v$, Equation (4.27) can be written as

$$\tau = C_A|_{z=0} \int_0^{\zeta_{A,L}} \frac{\partial\zeta_A}{|\mathbb{R}_A|} \tag{4.28}$$

The integral on the right-hand side also occurs in calculation of the reaction time of a batch reactor (see Eq. 4.20). Apparently, for constant density, the reaction time for a batch reactor corresponds to the residence time in a plug-flow reactor. From a physical viewpoint this is because in a plug-flow reactor the reaction mixture flows like a plug through a tube. This plug does not mix with other plugs and therefore can be regarded as a "small batch reactor" by itself, with a reaction time equal to the residence time in the tube.

Figure 13. Microscale mass balance for tubular plug-flow reactor with total volume $V = SL$

Figure 14. $E(t)$ (A) and $E(\theta)$ (B) diagrams for a plug-flow reactor

Conversion calculations for the plug-flow reactor can be done in a similar manner as for the batch reactor. Thus, for first-order kinetics,

$$|\mathbb{R}_A| = k\,C_A|_{z=0}\,(1-\zeta_A) \tag{4.29}$$

and Equation (4.28) yields

$$\zeta_A = 1 - e^{-k\tau} \tag{4.30}$$

A plug-flow reactor has no spread in residence time because the fluid is supposed to flow like a plug through the reactor. This means that the

input signal can be found back in the outlet with a time delay equal to the residence time. This is shown for the $E(t)$ and $E(\theta)$ diagrams in Figure 14. The RTD variance, therefore, must be zero in a plug-flow reactor:

$$\sigma_t^2 = \int_0^\infty (t-\bar{t})^2 \, E(t) \, \partial t = 0 \tag{4.31}$$

4.2.4. Continuous, Ideally Stirred Tank Reactor (CISTR)

A CISTR is a tank reactor whose contents are assumed to be "ideally mixed," so that conditions are the same throughout the tank and equal to conditions at the outlet (see Fig. 15). A steady-state material balance for the CISTR gives

$$\varphi_v \left(C_{\mathrm{A,in}} - C_{\mathrm{A}}\right) = |\mathbb{R}_{\mathrm{A}}| V \tag{4.32}$$

Introducing the relative degree of conversion ζ_{A}

$$\zeta_{\mathrm{A}} = \frac{C_{\mathrm{A,in}} - C_{\mathrm{A}}}{C_{\mathrm{A,in}}} \tag{4.33}$$

and assuming constant density of the reaction mixture yield

$$\tau = C_{\mathrm{A,in}} \frac{\zeta_{\mathrm{A}}}{|\mathbb{R}_{\mathrm{A}}|} \tag{4.34}$$

(cf. Eqs. 4.20 and 4.28). Again, τ is the holding time, or average residence time if adsorption effects are negligible.

Figure 15. Schematic of a continuously operated, ideally stirred tank reactor (CISTR)

For example, in a first-order reaction where

$$|\mathbb{R}_{\mathrm{A}}| = k C_{\mathrm{A,in}} \left(1 - \zeta_{\mathrm{A}}\right) \tag{4.35}$$

Equation (4.34) yields

$$k\tau = \frac{\zeta_{\mathrm{A}}}{1-\zeta_{\mathrm{A}}} \Leftrightarrow \zeta_{\mathrm{A}} = \frac{k\tau}{1+k\tau} \tag{4.36}$$

The E diagram for a CISTR can be derived from a material balance after an ideal δ-pulse has been injected in the inlet stream. The pulse is immediately distributed over the entire reactor; furthermore, the concentration remains the same throughout the reactor and equals the outlet concentration. Assuming constant density of the reaction mixture gives

$$V \frac{\partial C_{\mathrm{T}}}{\partial t} = -\varphi_v C_{\mathrm{T}} \tag{4.37}$$

where C_{T} is the tracer concentration. Introducing the holding time $\tau = V/\varphi_v$ yields

$$\frac{\partial C_{\mathrm{T}}}{\partial t} = -\frac{C_{\mathrm{T}}}{\tau} \tag{4.38}$$

The initial condition is

$$t = 0 \Rightarrow C_{\mathrm{T}} = \frac{n_{\mathrm{T},0}}{V} \tag{4.39}$$

where $n_{\mathrm{T},0}$ equals the total number of moles of tracer injected in the pulse at $t = 0$. After integration, Equation (4.38) yields

$$C_{\mathrm{T}} = \frac{n_{\mathrm{T},0}}{V} \mathrm{e}^{-t/\tau} = \frac{n_{\mathrm{T},0}}{V} \mathrm{e}^{-\theta} \tag{4.40}$$

To find the E diagram, this equation must be normalized; i.e., the property $\int_0^\infty E(\theta) \, \partial\theta = 1$ must be adhered to. This gives

$$E(\theta) = \frac{\frac{n_{\mathrm{T},0}}{V} \mathrm{e}^{-\theta}}{\int_0^\infty \frac{n_{\mathrm{T},0}}{V} \mathrm{e}^{-\theta} \, \partial\theta} = e^{-\theta} \tag{4.41}$$

The $E(t)$ diagram reads, according to Equation (4.12),

$$E(t) = \frac{\mathrm{e}^{-t/\tau}}{\tau} \tag{4.42}$$

The result is plotted in Figure 16.

Now, because of the spread in the RTD, the variance does not equal zero. Equation (4.7) shows that for a CISTR,

$$\sigma_t^2 = \int_0^\infty (t-\tau)^2 \, E(t) \, \partial t = \tau^2 \tag{4.43}$$

For a detailed treatment of macromixing, see [8]

Figure 16. $E(t)$ and $E(\theta)$ diagrams for a continuously operated, ideally stirred tank reactor (CISTR)

4.3. Micromixing

When applying the above models to real reactor systems, the question remains whether these models reflect the real mixing behavior closely enough to predict reactor performance accurately. Especially in the case of non-first-order reactions or reactions with separate reactant inlets, the models should describe accurately enough not only the gross overall mixing behavior, but also the detailed intermixing of different fluid elements. To avoid problems related to micromixing, the assumption of an ideal microfluid has been made above. This is not necessarily true in practice.

For a continuously operated vessel, which shows the residence time of an ideal mixer, Equation (4.42) holds:

$$E(t) = \frac{e^{-t/\tau}}{\tau}$$

The different states of micromixing are illustrated in Figure 17. Three types can be distinguished:

1) The continuous, ideally stirred tank reactor (CISTR), a mixer that contains a microfluid
2) The continuous, segregated stirred tank reactor (CSSTR), a completely segregated mixer (here the fluid consists of lumps that travel through the reactor without exchanging matter with their neighbors)
3) The continuous, stirred-tank reactor (CSTR), which is a partially segregated mixer

Typical practical problems in which micromixing may have to be taken into account are

1) Reactors processing viscous fluids in which rapid reactions occur (e.g., polymerization reactors in which melt or solution polymerization is carried out)
2) Reactions in emulsions where the dispersed droplets have finite coalescence – redispersion rates
3) Reactors where rapid reactions occur between reactants that are fed through separate inlet points
4) Precipitation reactions
5) Highly nonisothermal reactors (e.g., flames)

For these systems an exact description is not possible and will probably not be practical for a long time to come. In many cases it is possible to calculate the extremes between which conversion and selectivity can be influenced by micromixing. In the following examples, only isothermal systems with constant density are considered.

In Figure 18 the reaction rate is depicted as a function of the concentration for an n-th-order reaction (i.e., $-\mathbb{R}_A- = k\,C_A^n$). Consider two elements 1 and 2 with equal volume, and assume that those elements leave the reactor at the same moment. The concentration C_A in the elements is not the same because the residence times of elements 1 and 2 are different. If the elements are not mixed (no micromixing), the average reaction rate for the two elements follows from

$$|\overline{\mathbb{R}_A}| = k\frac{C_{A,1}^n + C_{A,2}^n}{2} \tag{4.44}$$

If the two elements had in fact been mixed (complete micromixing), the reaction rate $-\mathbb{R}_A-_{\text{mixed}}$ would have been

$$|\mathbb{R}_A|_{\text{mixed}} = k\left(\frac{C_{A,1} + C_{A,2}}{2}\right)^n \tag{4.45}$$

This leads to the following conclusions:

Figure 17. Possible states of micromixing in a stirred vessel
A) CSSTR, complete segregation; B) CISTR, ideal micromixing; C) CSTR, intermediate micromixing

1) $n < 1 \Rightarrow -\overline{\mathbb{R}_A} - < - \mathbb{R}_A -_{\text{mixed}}$ that is, for reaction orders below unity the absence of micromixing decreases the overall reaction rate
2) $n = 1 \Rightarrow -\overline{\mathbb{R}_A} - = - \mathbb{R}_A -_{\text{mixed}}$ that is, for a reaction order of unity, micromixing does not influence the rate
3) $n > 1 \Rightarrow -\overline{\mathbb{R}_A} - > - \mathbb{R}_A -_{\text{mixed}}$ that is, for reaction orders larger than unity the absence of micromixing increases the overall reaction rate

The intermixing of elements 1 and 2, which leave the reactor at the same moment, is not detectable by measuring the RTD function, so for non-first-order reactions the RTD does not provide sufficient data to calculate the conversion. For first-order reactions in which the degree of micromixing has no effect, the conversion can be calculated from the RTD.

Figure 18. Influence of mixing on average reaction rate of two equal-volume fluid elements 1 and 2 that leave the reactor at the same time

For reactors with separate feed inlet points for different reactants, micromixing effects may be as important for plug-flow reactors as for CSTRs. In the extreme case of almost no micromixing, hardly any reaction occurs because the reactants remain in different aggregates and cannot come in contact with each other. These systems are discussed in [21].

Here the case is considered in which the reactants are premixed. For a plug-flow reactor with premixed reactants, the concept of micromixing is irrelevant because all elements that pass through the reactor can mix only with elements of exactly the same age. In a CSTR, two extreme states of micromixing exist: the microfluid (CISTR) and the completely segregated fluid (CSSTR). The first case has already been discussed; the latter is discussed here.

Completely Segregated Fluid. The fraction of aggregates having a residence time between t and $t + \partial t$ is $E(t)\,\partial t$, which follows directly from the definition of E given above. The average reactant concentration C_A in these aggregates equals the concentration $C_{A,\,BR}(t)$ obtained for a batch reactor in time t. This can be understood if one realizes that the aggregate has not mixed at all with other aggregates (complete segregation) and hence can be regarded a "small batch reactor" traveling through the CSSTR to the outlet. The average concentration at the CSSTR outlet is the sum of the products of concentration times fraction for all aggregates:

$$\overline{C_A} = \int_0^\infty C_{A,\,BR}(t)\,E(t)\,\partial t \tag{4.46}$$

In terms of the relative degree of conversion,

$$\zeta_{A,\,CSSTR} = \int_0^\infty \zeta_{A,\,BR}(t)\,E(t)\,\partial t \tag{4.47}$$

where $\zeta_{\mathrm{A,\,BR}}(t)$ is the conversion reached in a batch reactor after reaction time t. For a first-order reaction in a CSSTR, according to Equations (4.22), (4.42) and (4.47),

$$\zeta_{\mathrm{A,\,CSSTR}} = \int_0^\infty \left(1 - \mathrm{e}^{-kt}\right) \frac{\mathrm{e}^{-t/\tau}}{\tau}\, \partial t = \frac{k\tau}{1+k\tau} \tag{4.48}$$

If this is compared to Equation (4.36), for first-order reactions $\zeta_{\mathrm{A,\,CSSTR}} = \zeta_{\mathrm{A,\,CISTR}}$; this demonstrates again that for first-order reactions micromixing has no effect, as concluded from Figure 18.

For reaction orders not equal to unity, however, the situation is different. Below, the relative degree of conversion is calculated for a batch reactor, a plug-flow reactor (PFR), a CISTR, and a CSSTR for zero-order kinetics:

$$|\mathbb{R}_{\mathrm{A}}| = \begin{cases} k & C_{\mathrm{A}} \geq 0 \\ 0 & C_{\mathrm{A}} < 0 \end{cases} \tag{4.49}$$

At this point the Damköhler number *Da* should be defined:

$$Da = \begin{cases} \frac{k\,t}{C_{\mathrm{A,\,0}}} & \text{(BR)} \\ \frac{k\,\tau}{C_{\mathrm{A}}|_{z=0}} & \text{(PFR)} \\ \frac{k\,\tau}{C_{\mathrm{A,\,in}}} & \text{(CISTR/CSSTR)} \end{cases} \tag{4.50}$$

Then, for the different reactors, the following holds:

1) *Batch Reactor*. According to Equation (4.18),

$$\frac{\partial C_{\mathrm{A}}}{\partial t} = -\begin{cases} k & \text{for } C_{\mathrm{A}} \geq 0 \\ 0 & \text{for } C_{\mathrm{A}} < 0 \end{cases} \Rightarrow$$

$$\frac{\partial \zeta_{\mathrm{A}}}{\partial Da} = \begin{cases} 1 & \text{for } \zeta_{\mathrm{A}} \leq 1 \\ 0 & \text{for } \zeta_{\mathrm{A}} > 1 \end{cases} \tag{4.51}$$

This must be solved subject to

$$Da = 0 \Rightarrow \zeta_{\mathrm{A}} = 0 \tag{4.52}$$

which gives

$$\zeta_{\mathrm{A,\,BR}} = \begin{cases} Da & \text{for } Da \leq 1 \\ 1 & \text{for } Da \geq 1 \end{cases} \tag{4.53}$$

2) *Plug-flow reactor*. A micromaterial balance for a slice ∂z gives

$$u\frac{\partial C_{\mathrm{A}}}{\partial z} = -\begin{cases} k & \text{for } C_{\mathrm{A}} \geq 0 \\ 0 & \text{for } C_{\mathrm{A}} < 0 \end{cases} \Rightarrow$$

$$\frac{\partial \zeta_{\mathrm{A}}}{\partial\,(z/L)} = \begin{cases} Da & \text{for } \zeta_{\mathrm{A}} \leq 1 \\ 0 & \text{for } \zeta_{\mathrm{A}} > 1 \end{cases} \tag{4.54}$$

which is to be solved subject to

$$z = 0 \Rightarrow \zeta_{\mathrm{A}} = 0 \tag{4.55}$$

Integration to $z = L$ gives exactly the same result as found for the batch reactor (Eq. 4.53):

$$\zeta_{\mathrm{A,\,PFR}} = \begin{cases} Da & \text{for } Da \leq 1 \\ 1 & \text{for } Da > 1 \end{cases} \tag{4.56}$$

3) *CISTR*. The material balance (Eq. 4.32) now gives

$$\varphi_v\left(C_{\mathrm{A,\,in}} - C_{\mathrm{A}}\right) = \begin{cases} kV & \text{for } C_{\mathrm{A}} \geq 0 \\ 0 & \text{for } C_{\mathrm{A}} < 0 \end{cases} \tag{4.57}$$

This can be rewritten to again yield Equation (4.53):

$$\zeta_{\mathrm{A,\,CISTR}} = \begin{cases} Da & \text{for } Da \leq 1 \\ 1 & \text{for } Da > 1 \end{cases} \tag{4.58}$$

4) *CSSTR*. Now according to Equation (4.47),

$$\begin{aligned} \zeta_{\mathrm{A,\,CSSTR}} &= \int_0^\infty \zeta_{\mathrm{A,\,BR}}(t)\, E(t)\, \partial t \\ &= \int_0^{\frac{C_{\mathrm{A,in}}}{k}} \left(\frac{k\,t}{C_{\mathrm{A,in}}}\right)\left[\frac{1}{\tau}\exp\left(-\frac{t}{\tau}\right)\right] \partial t \\ &+ \int_{\frac{C_{\mathrm{A,in}}}{k}}^\infty \left[\frac{1}{\tau}\exp\left(-\frac{t}{\tau}\right)\right] \partial t \\ &= \int_0^{\frac{1}{Da}} \theta \mathrm{e}^{-\theta}\, \partial\theta + \int_{\frac{1}{Da}}^\infty \mathrm{e}^{-\theta}\, \partial\theta \end{aligned} \tag{4.59}$$

which finally gives

$$\zeta_{\mathrm{A,\,CSSTR}} = Da\left[1 - \exp\left(-\frac{1}{Da}\right)\right] \tag{4.60}$$

Thus, for zeroth-order reactions $\zeta_{\mathrm{A,\,CSSTR}} \neq \zeta_{\mathrm{A,\,CISTR}}$ (see Fig. 19).

As expected from Figure 18, $\zeta_{A,\,CSSTR} < \zeta_{A,\,CISTR}$ because the reaction order is lower than unity. In a CISTR the conversion can reach 100 % for a finite residence time $\tau = C_{A,\,in}/k$, which follows from Equations (4.50) and (4.58). For a CSSTR, however, conversion in principle never reaches 100 %. Zeroth-order reactions are therefore very sensitive to micromixing at high conversions, so they are attractive as model reactions for assessing micromixing. Regretfully, many reactions that appear to be zeroth order at high reactant concentrations increase in apparent reaction order at higher conversions. This is the case, for example, if the reaction can be described by Langmuir or Michaelis – Menten kinetics as discussed in Sections 3.3.3 and 3.3.4.

Figure 19. Influence of micromixing on the conversion of a zeroth-order chemical reaction in a stirred vessel (CSTR) a) Micromixed reactor; b) Completely segregated mixer

Intermediate Degree of Micromixing. The case of an intermediate degree of micromixing (e.g., between a microfluid and a completely segregated fluid) is very complex. Models describing intermediate micromixing usually do not give a clear physical picture of the actual phenomena but merely try to cover the span between the minimum and maximum degree of mixing by one or two adjustable parameters. These parameters must be determined experimentally (e.g., by measuring the conversion of a chemical reaction with non-first-order kinetics). A disadvantage is that the resulting micromixing parameter is merely a fitting parameter, which can have different values (e.g., for different conversions or reaction kinetics).

A more refined concept has been proposed by Weinstein and Adler [22] and improved by Villermaux and Zoulalian [23].

4.4. Sequence of Mixing

For the sake of completeness it should be mentioned here that macromixing and micromixing together are still not sufficient to give a unique prediction of the conversion. For non-first-order reactions the sequence of mixing is also relevant. Since, like macromixing, the sequence of mixing is not a macrokinetic, but a reactor-level phenomenon, the subject is touched on only briefly here by way of an example.

In Figure 20 the residence-time distribution of a plug-flow reactor and a CISTR in series is shown. Two cascades can be distinguished: the PFR before the CISTR or the PFR after the CISTR. The RTDs for both cascades are the same; hence, macromixing is the same for both cascades. Furthermore, a microfluid is assumed so the degree of micromixing is also the same. The only difference between the two cascades is the sequence of mixing.

Figure 20. $E(t)$ diagram for cascades I and II
The order of the arrangement has no influence on the RTD.

For second-order reactions $-\mathbb{R}_A - = k\,C_A^2$ the conversion for both cascades can be calculated from

1) For cascade I:

$$\zeta_A = 1 + \frac{1}{2kC_{A,\,in}\tau_2}\left(1 - \sqrt{1 + 4\frac{kC_{A,\,in}\tau_2}{1 + kC_{A,\,in}\tau_1}}\right) \tag{4.61}$$

2) For cascade II:

$$\zeta_A = 1 + \frac{1 - \sqrt{1 + 4kC_{A,\,in}\tau_2}}{2kC_{A,\,in}\tau_2 + kC_{A,\,in}\tau_1\left(1 - \sqrt{1 + 4kC_{A,\,in}\tau_2}\right)} \tag{4.62}$$

This is illustrated in Figure 21. Obviously, the sequence of mixing can have a pronounced influence on the conversion of non-first-order reactions.

Figure 21. Influence of the sequence of mixing for a second-order reaction
a) CISTR; b) Cascade II (CISTR – plug-flow reactor); c) Cascade I (plug-flow reactor – CISTR); d) Plug-flow reactorCascades I and II are a PFR – CISTR and CISTR – PFR line up, respectively, with the CISTR and PFR having equal residence times $\tau/2$. In all cases a – d there are microfluids. Hence, only the sequence of mixing is changed.

5. Macrokinetics: Multiphase Systems – Part I: Mass Transfer without Reaction

5.1. Introduction

In this section, simple models describing the rate of mass transfer to or from an interface are summarized briefly. For a more detailed treatment, see → Transport Phenomena, Chap. 3.

If transport of component A is determined by *molecular diffusion* only (i.e., no flow of fluid), the net transport can be approximated by Fick's first law:

$$(J_A)_x = -\frac{C}{1-\kappa_A}\mathbb{D}_A\frac{\partial\kappa_A}{\partial x} \tag{5.1}$$

with $(J_A)_x$ the molar flux of A at location x (mol m^{-2} s^{-1}), C the total molar concentration (mol/m^3), κ_A the mole fraction of component A, $\mathbb{D}_A$ the coefficient of molecular diffusion of A (m^2/s), and x the coordinate perpendicular to the interface (m). In the majority of cases involving mass transfer with reaction, the total molar concentration does not change significantly near the interface. Furthermore, κ_A is often much less than 1. Then Fick's law reduces to

$$(J_A)_x = -\mathbb{D}_A\frac{\partial C_A}{\partial x} \tag{5.2}$$

In what follows, generally this simple expression (Eq. 5.2) is used. However, the validity of Equation (5.2) must always be checked. If large pressure, temperature, or mole fraction gradients occur in a system, a more rigorous approach must be chosen. For such systems, even the validity of Equation (5.1) is questionable, and use, for example, of the *dusty-gas model* is recommended (e.g., [24]).

If Equation (5.2) holds, a general material balance in Cartesian coordinates takes the following appearance:

$$\begin{aligned}
&\frac{\partial C_A}{\partial t} = && \text{Accumulation}\\
&-\frac{\partial(u_x C_A)}{\partial x} - \frac{\partial(u_y C_A)}{\partial y} - \frac{\partial(u_z C_A)}{\partial z} && \text{Convection}\\
&+\mathbb{D}_A\left(\frac{\partial^2 C_A}{\partial x^2} + \frac{\partial^2 C_A}{\partial y^2} + \frac{\partial^2 C_A}{\partial z^2}\right) && \text{Diffusion}\\
&-|\mathbb{R}_A| && \text{Reaction}
\end{aligned} \tag{5.3}$$

Note the minus sign in front of — $\mathbb{R}_A$ —: it is assumed that A is a reactant so that A is consumed.

For systems with constant density, Equation (5.3) can be simplified to

$$\frac{\partial C_A}{\partial t} = -u_x\frac{\partial C_A}{\partial x} - u_y\frac{\partial C_A}{\partial y} - u_z\frac{\partial C_A}{\partial z} + \mathbb{D}_A\left(\frac{\partial^2 C_A}{\partial x^2} + \frac{\partial^2 C_A}{\partial y^2} + \frac{\partial^2 C_A}{\partial z^2}\right) - |\mathbb{R}_A| \tag{5.4}$$

Often, further simplifications are possible. For example, for mass transfer in stagnant systems (no convection), $u_x = u_y = u_z = 0$; hence

$$\frac{\partial C_A}{\partial t} = \mathbb{D}_A\left(\frac{\partial^2 C_A}{\partial x^2} + \frac{\partial^2 C_A}{\partial y^2} + \frac{\partial^2 C_A}{\partial z^2}\right) - |\mathbb{R}_A| \tag{5.5}$$

which for steady-state conditions becomes

$$\mathbb{D}_A\left(\frac{\partial^2 C_A}{\partial x^2} + \frac{\partial^2 C_A}{\partial y^2} + \frac{\partial^2 C_A}{\partial z^2}\right) = |\mathbb{R}_A| \tag{5.6}$$

Alternatively, in the case of mass transfer without reaction (— $\mathbb{R}_A$ — = 0), Equation (5.5) yields

$$\frac{\partial \zeta C_A}{\partial t} = \mathbb{D}_A\left(\frac{\partial^2 C_A}{\partial x^2} + \frac{\partial^2 C_A}{\partial y^2} + \frac{\partial^2 C_A}{\partial z^2}\right) \tag{5.7}$$

which for steady-state conditions becomes

$$\frac{\partial^2 C_A}{\partial x^2} + \frac{\partial^2 C_A}{\partial y^2} + \frac{\partial^2 C_A}{\partial z^2} = 0 \tag{5.8}$$

Theoretically, the rate of mass transfer can be calculated from one of the Equations (5.3) to (5.8). The solution gives the concentration gradient at the interface, from which the molar flux of A through the interface can be calculated:

$$J_A = -\mathbb{D}_A \left(\frac{\partial C_A}{\partial x}\right)_{x=0} \tag{5.9}$$

In practice, however, this procedure is generally not applicable because of a lack of knowledge of the exact flow profile near the interface. Exceptions are mass transfer into or from quiescent media and in laminar flow systems. Therefore, more simple models are generally used, which lump the rate of mass transfer into one parameter. The three most widely used models are discussed below. Finally, the concept of the *mass-transfer coefficient* is introduced.

5.2. Penetration Models

The first penetration model originates from Higbie [25], where the mass-transfer process is described as follows: The interface is assumed to be covered with small stagnant fluid elements and mass transfer occurs into the elements. After a contact time τ with the interface, the elements return to the well-mixed bulk of the fluid from which they came, while new elements originating from the bulk take their place at the interface. Coming from the bulk, all stagnant elements have a uniform initial concentration $\overline{C_A}$. At the interface, mass transfer takes place by diffusion. This diffusion process is essentially transient. Figure 22 is a qualitative sketch of the concentration profiles versus the distance from the interface for several times. The depth of penetration of A into the element is assumed to be small with respect to the thickness of the element δ. Because this is a stagnant medium with no chemical reaction, Equation (5.7) applies. Since diffusion occurs perpendicular to the interface, only the x coordinate perpendicular to the interface is relevant and Equation (5.7) reduces to

$$\frac{\partial C_A}{\partial t} = \mathbb{D}_A \frac{\partial^2 C_A}{\partial x^2} \tag{5.10}$$

This partial differential equation must be solved subject to the initial condition

$$t = 0 \text{ and } x > 0 \Rightarrow C_A = \overline{C_A} \tag{5.11}$$

and the boundary conditions

$$t > 0 \text{ and } x = 0 \Rightarrow C_A = C_{A,i} \tag{5.12}$$

$$t > 0 \text{ and } x \to \infty \Rightarrow C_A \to \overline{C_A} \tag{5.13}$$

The last boundary condition can be used because the penetration depth is much smaller than the thickness of the element, so a semi-infinite medium can be assumed.

Figure 22. Concentration profiles in stagnant fluid element as a function of time (τ = maximum time: contact time in the Higbie penetration model)

The solution found for Equations (5.10)–(5.13) is

$$\frac{C_{A,i} - C_A}{C_{A,i} - \overline{C_A}} = \operatorname{erf}\left(\frac{x}{2\sqrt{\mathbb{D}_A t}}\right) \tag{5.14}$$

Differentiation of Equation (5.14) gives the molar flux of A through the interface:

$$J_A = -\mathbb{D}_A \left(\frac{\partial C_A}{\partial x}\right)_{x=0} = \sqrt{\frac{\mathbb{D}_A}{\pi t}}\left(C_{A,i} - \overline{C_A}\right) \tag{5.15}$$

This shows that the mass-transfer rate decreases with increasing time, which is caused by a decrease of $\partial C_A/\partial x$ at the interface as illustrated in Figure 22. The time-average molar flux of A for the entire contact time τ that the stagnant element remains at the interface equals

$$\overline{J_A} = \frac{1}{\tau}\int_0^\tau J_A\,\partial t = 2\sqrt{\frac{\mathbb{D}_A}{\pi\tau}}\left(C_{A,i} - \overline{C_A}\right) \tag{5.16}$$

The rate of mass transfer can be lumped in the parameter τ, which is called the *contact time* or sometimes the *penetration time*. Occasionally τ can be calculated from first principles (e.g., for model reactors such as the laminar jet or laminar film reactor [8]). For completely mobile bubbles it is suggested [25] that

$$\tau \approx \frac{d_b}{u_b} \tag{5.17}$$

with d_b the bubble diameter (m) and u_b the bubble rise velocity (m/s). However, for most applications, τ must be regarded as a fit parameter and must be obtained from experimental data.

A modification of the Higbie penetration model has been developed by DANCKWERTS [26]. Instead of a constant contact time τ, he assumes that the chance of a surface element being replaced within a given time is independent of its age. Thus, each element has an equal chance of being replaced during the next time unit. The fraction of elements that is replaced per unit time is s (s^{-1}). Thus, the following can be derived:

$$\overline{J_A} = \sqrt{\mathbb{D}_A s}\left(C_{A,i} - \overline{C_A}\right) \tag{5.18}$$

The penetration model of DANCKWERTS [26] is also known as the *surface renewal model*.

5.3. Stagnant Film Model

The stagnant film model is based on the following assumptions:

1) The fluid can be divided into two zones: a stagnant film near the interface with thickness δ and a well-mixed bulk behind it in which no concentration gradients occur
2) Mass transfer is a stationary process

Since a stagnant film, no reaction, and a steady state are assumed, Equation (5.8) applies in the film:

$$\frac{\partial^2 C_A}{\partial x^2} + \frac{\partial^2 C_A}{\partial y^2} + \frac{\partial^2 C_A}{\partial z^2} = 0 \quad \text{for} \quad 0 < x < \delta \tag{5.19}$$

If the radius of curvature of the interface is large compared to the film thickness and the x coordinate is perpendicular to the interface, Equation (5.19) reduces to

$$\frac{\partial^2 C_A}{\partial x^2} = 0 \quad \text{for} \quad 0 < x < \delta \tag{5.20}$$

This equation must be solved subject to the boundary conditions (see Fig. 23):

$$x = 0 \Rightarrow C_A = C_{A,i} \tag{5.21}$$

$$x = \delta \Rightarrow C_A = \overline{C_A} \tag{5.22}$$

Solving Equations (5.20) – (5.22) gives

$$\frac{C_{A,i} - C_A}{C_{A,i} - \overline{C_A}} = \frac{x}{\delta} \tag{5.23}$$

as illustrated in Figure 23. The molar flux of A then follows from

$$J_A = -\mathbb{D}_A \left(\frac{\partial C_A}{\partial x}\right)_{x=0} = \frac{\mathbb{D}_A}{\delta}\left(C_{A,i} - \overline{C_A}\right) \tag{5.24}$$

From a physical point of view, the film model is often not realistic because a stagnant film does not exist near an interface. The advantage of the model is its simplicity and mediative power.

All three models discussed above have in common the fact that the hydrodynamic conditions near the interface are lumped into one parameter: τ, s, or δ. For most applications this parameter must be regarded as a fit parameter to be obtained from experimental data. Because of the similarity of results, the application of more complicated (and possibly more realistic) mass-transfer models does not result in substantially better (i.e., more accurate) predictions (e.g., [27]). In particular, the knowledge of hydrodynamic, physical, and kinetic data is often not accurate enough. This explains why the simple film model is also applied in mass transfer to reaction problems in which the film theory is clearly an oversimplification with respect to the hydrodynamics of the system.

Figure 23. Concentration profile in the fluid film according to stagnant film theory

5.4. Mass-Transfer Coefficients

In practice the concept of the mass-transfer coefficient is often used. A mass-transfer coefficient is defined as

$$k_{\mathrm{l,A}} \quad \text{or} \quad k_{\mathrm{g,A}} \equiv \left| \frac{(J_{\mathrm{A}})_{\mathrm{phys}}}{C_{\mathrm{A,i}} - \overline{C}_{\mathrm{A}}} \right| \tag{5.25}$$

The subscript "phys" is added to J_A to stress the fact that the definition is restricted to the case in which A does not undergo a chemical reaction: only physical mass transfer of A is considered. The mass-transfer coefficients $k_{l,A}$ and $k_{g,A}$ have the dimension meters per second. If the molar fraction of A is low enough (< 0.1), the numerical values of $k_{l,A}$ and $k_{g,A}$ depend mainly on the geometry of the system, the physical constants (the viscosity, density, and diffusion coefficient), and the local hydrodynamics.

Substituting Equations (5.16), (5.18), and (5.24) in Equation (5.25) shows that each of the models discussed above gives its own relation for the mass-transfer coefficient:

$$k_{\mathrm{l,A}}/k_{\mathrm{g,A}} = \begin{cases} 2\sqrt{\frac{\mathbb{D}_{\mathrm{A}}}{\pi\,\tau}} & \textit{Higbie penetration model} \\ \sqrt{\mathbb{D}_{\mathrm{A}}\,s} & \textit{Surface renewal model} \\ \frac{\mathbb{D}_{\mathrm{A}}}{\delta} & \textit{Film theory} \end{cases} \tag{5.26}$$

The value of these relations is rather limited, because the parameters τ, s, and δ depend on the geometry of the system, the physical constants, and local hydrodynamics. In fact, τ, s, and δ are usually calculated from experimental mass-transfer coefficients according to the above equations. In calculating the rate of mass transfer of component A from one phase to another, the mass-transfer coefficients of both phases must be considered, as well as m, the distribution coefficient of A between the two phases. For example, for a gas liquid interface, a mass balance (see Fig. 24) yields

$$J_{\mathrm{A}} = k_{\mathrm{g,A}}\left(\overline{C_{\mathrm{A,g}}} - C_{\mathrm{A,i,g}}\right) = k_{\mathrm{l,A}}\left(\overline{C_{\mathrm{A,l}}} - C_{\mathrm{A,i,l}}\right) \tag{5.27}$$

For nearly all practical cases, the two phases at the interface can be assumed to be in equilibrium:

$$C_{\mathrm{A,i,l}} = m C_{\mathrm{A,i,g}} \tag{5.28}$$

The equilibrium constant or dimensionless distribution coefficient m generally depends on the physical properties of both phases (composition, pressure) and is usually strongly dependent on temperature. At a constant value of m, the proportionality given by Equation (5.28) is called Henry's law for gas – liquid equilibria and Nernst's law for liquid – liquid equilibria.

Figure 24. Concentration profiles near a gas – liquid interface in absorption
A) General case; B) Negligible gas-phase resistance; C) Negligible liquid-phase resistance; D) Equilibrium

Combining Equations (5.27) and (5.28) allows the interface concentrations to be eliminated and yields

$$J_A = \left(\frac{1}{mk_{l,A}} + \frac{1}{k_{g,A}}\right)^{-1} \left(\overline{C_{A,g}} - \frac{\overline{C_{A,l}}}{m}\right) \quad (5.29)$$

For $mk_{l,A}/k_{g,A} << 1$, the gas-phase resistance is negligible, and Equation (5.29) reduces to

$$J_A = mk_{l,A} \left(\overline{C_{A,g}} - \frac{\overline{C_{A,l}}}{m}\right) \quad (5.30)$$

For $mk_{l,A}/k_{g,A} >> 1$, the liquid-phase resistance is negligible, and Equation (5.29) reduces to

$$J_A = k_{g,A} \left(\overline{C_{A,g}} - \frac{\overline{C_{A,l}}}{m}\right) \quad (5.31)$$

Mass transfer stops for $\overline{C_{A,l}} = m\,\overline{C_{A,g}}$. Figure 24 qualitatively shows concentration profiles for the general case and for the asymptotic values.

6. Macrokinetics: Multi-phase Systems – Part II: Mass Transfer with Reaction

In the following sections, two cases of mass transfer with reaction are discussed: the case in which mass transfer and reaction occur in series, and the case of mass transfer with simultaneous reaction. The manner in which the two cases can be combined is also shown.

6.1. Mass Transfer with Reaction in Series

6.1.1. Introduction

The following steps occur in the general case of a reaction at the surface of a porous particle (e.g., catalyst):

1) Mass transfer of the reactants from the bulk of the fluid to the external surface of the particle
2) Transport of the reactants through the pores into the particle by diffusion
3) Adsorption of reactants on the solid surface
4) Chemical conversion in the adsorbed state
5) Desorption of products
6) Transport of products through the pores to the external surface of the particle
7) Transport of products from the external surface to the bulk

In the case of nonporous particles, steps 2 and 6 do not occur. In what follows, the assumption is made that the particles are not porous. Steps 2 and 6 come under simultaneous mass transfer and reaction, and are treated later. If steps 2 and 6 are absent, mass transfer and reaction occur in series. If only external mass transfer occurs, a rigorous analysis of this problem can be obtained by simply considering the values of the mass-transfer coefficients of each of the components. Whether the values of those coefficients are estimated with the Higbie penetration, surface renewal, or stagnant film model is not relevant: their value alone suffices. Consequently, for the analysis below, a distinction need not be made among the three models; therefore, they are not considered in this section.

6.1.2. Monomolecular First-Order Kinetics

Reactant A is assumed to be converted according to a first-order reaction. For convenience a chemical reaction rate — $\mathbb{R}''_A$ — is defined per unit of external surface:

$$|\mathbb{R}''_A| = \frac{V_p}{A_p} |\mathbb{R}_A|_p \quad (6.1)$$

where — $\mathbb{R}''_A$ — is the rate based on the external surface area of the pellet (moles of A per square meter of external pellet surface per second); V_p the pellet volume (m^3); A_p the external surface area of the pellet (m^2); and — $\mathbb{R}_A$ —$_p$ the reaction rate based on the pellet volume (moles of A per cubic meter of pellet volume per second). The latter parameter is discussed below in further detail. Corresponding to the reaction rate per unit surface is a surface kinetic constant k''_r for first-order kinetics:

$$|\mathbb{R}''_A| = k''_r C_{A,i} \quad (6.2)$$

where $C_{A,i}$ is the reactant concentration in the direct vicinity of the pellet surface (mol/m^3). Since first-order kinetics apply, the dimension of k''_r is meters per second.

If, for example, a gas – solid reaction is assumed, the stationary conversion rate can be calculated from Equation (6.2) together with

$$J_A = k_g\left(\overline{C_A} - C_{A,i}\right) \tag{6.3}$$

and under steady-state conditions

$$|\mathbb{R}''_A| = J_A \tag{6.4}$$

where k_g is the mass-transfer coefficient of A. Elimination of the unknown concentration $C_{A,i}$ gives the overall conversion rate

$$J_A = \left(\frac{1}{k''_r} + \frac{1}{k_g}\right)^{-1} \overline{C_A} \tag{6.5}$$

The two asymptotic solutions are (see Fig. 25)

1) The fast reaction regime for $k''_r/k_g >> 1$. The rate of mass transfer completely limits the conversion rate, which follows from

$$J_A = k_g \overline{C_A} \tag{6.6}$$

In this regime the conversion rate (hence, reactor capacity) can be enhanced by increasing the mass-transfer rate (e.g., by increasing the fluid velocity in the reactor or decreasing the average particle diameter).

2) The *slow reaction regime* for $k''_r/k_g << 1$. The chemical reaction rate completely limits the conversion rate, which now follows from

$$J_A = k''_r \overline{C_A} \tag{6.7}$$

In this regime, the conversion rate can be enhanced by increasing the chemical reaction rate, for example, by increasing the temperature of the reactor.

Figure 25. Two asymptotic concentration profiles for mass transfer and reaction in series (film theory)
A) Fast reaction regime; B) Slow reaction regime

6.1.3. Arbitrary Monomolecular Kinetics

The system analyzed above is easily extended to arbitrary kinetics. Langmuir kinetics are discussed here as an example. Then,

$$|\mathbb{R}''_A| = \frac{k''_r C_{A,i}}{1 + K C_{A,i}} \tag{6.8}$$

Combination with Equations (6.3) and (6.4) and elimination of $C_{A,i}$ give:

$$J_A = k_g \overline{C_A} \frac{2\beta}{1 + \alpha + \beta + \sqrt{(1 - \alpha + \beta)^2 + 4\alpha}}$$

$$\text{with} \quad \alpha = K\overline{C_A} \quad \text{and } \beta = \frac{k''_r}{k_g} \tag{6.9}$$

In the *slow reaction regime*, $k''_r/k_g << 1$ and thus $\beta \to 0$, Equation (6.9) becomes

$$J_A = k_g \overline{C_A} \frac{\beta}{1 + \alpha} = \frac{k''_r \overline{C_A}}{1 + K\overline{C_A}} \tag{6.10}$$

and mass-transfer limitation has no effect on the overall conversion rate.

In the *fast reaction regime* where $k''_r/k_g >> 1$ and $\beta \to \infty$, Equation (6.9) yields

$$J_A = k_g \overline{C_A} \tag{6.11}$$

Figure 26. Concentration profiles for mass transfer and reaction in series in a gas – liquid – solid system (film theory)

Hence, due to mass-transfer limitation, an apparent first-order kinetics is observed in the fast reaction regime, irrespective of the numerical value of the term $K\overline{C_A}$. The physical explanation is that although the value of the term $K\overline{C_A}$

may be large, in this regime $C_{A,i}$ is much smaller than $\overline{C_A}$, so that $KC_{A,i}$ is much smaller than unity and the adsorption term in Langmuir kinetics becomes negligible. From this, the conclusion can be drawn that mass-transfer limitation may cause an apparent change in the reaction order. Below, more examples illustrating this statement are presented. For other forms of arbitrary kinetics, expressions for the conversion rate analogous to Equation (6.9) are obtained in a similar way.

6.1.4. Multiple Phases

The system discussed in Sections 6.1.2 and 6.1.3 is also easily extended to a three-phase reactor with mass transfer and reaction in series: for example, a gas is absorbed in a liquid in which nonporous particles are suspended. Reaction occurs at the surface of the particles. Examples are the hydrogenation of organic liquids with a solid catalyst and the alkylation of a liquid reactant with gaseous ethylene, for example, and solid $AlCl_3$ as catalyst.

The concentration profile could be that shown in Figure 26. At the gas – liquid interface the assumed equilibrium is given by

$$C_{A,i,l} = m\,C_{A,i,g} \tag{6.12}$$

where m is the distribution coefficient. The parameter a_{gl} is defined as the specific gas – liquid surface area (m^{-1}) and a_{ls} as the specific catalyst particle area (m^{-1}), both per unit volume of dispersion. k_g is the gas-phase mass-transfer coefficient for the transfer from gas to liquid, and k_l and k_{ls} are the liquid-phase mass-transfer coefficients for the transfers from gas to liquid and liquid to solid, respectively (all with the dimension m/s). If first-order kinetics are assumed, then the *overall conversion rate* — R_A — is given by

$$\begin{aligned} |R_A| &= a_{ls} k_r'' C_{A,i,s} \\ &= a_{gl} k_g \left(\overline{C_{A,g}} - C_{A,i,g}\right) \\ &= a_{gl} k_l \left(C_{A,i,l} - \overline{C_{A,l}}\right) \\ &= a_{ls} k_{ls} \left(\overline{C_{A,l}} - C_{A,i,s}\right) \end{aligned} \tag{6.13}$$

Combining Equations (5.27) and (6.13) and eliminating the unknown concentrations $C_{A,i,g}$, $C_{A,i,l}$, $C_{A,i,s}$, and $\overline{C_{A,l}}$ give

$$|R_A| = \overline{C_{A,g}} \cdot \left(\frac{1}{a_{gl} k_g} + \frac{1}{m a_{gl} k_l} + \frac{1}{m a_{ls} k_{ls}} + \frac{1}{m a_{ls} k_r''}\right)^{-1} \tag{6.14}$$

Reactor capacity per unit volume appears to depend on four resistances in series: the gas-phase transfer resistance, two liquid-phase transfer resistances, and the kinetic resistance. The highest resistance limits the capacity of the reactor.

Implicit in the derivation of Equation (6.14) is the assumption that all solid particles are in the bulk of the liquid phase. However, for

$$\frac{1}{a_{ls} k_{ls}} + \frac{1}{a_{ls} k_r''} << \frac{1}{a_{gl} k_l} \tag{6.15}$$

the concentration of A in the bulk of the liquid approaches zero. Then, only the particles in the liquid film at the gas – liquid interface may be active; hence mass transfer and reaction are parallel steps instead of being in series. This problem has been studied by SADA et al. [28], [29].

6.1.5. Bimolecular Reactions

Here again a two-phase situation is assumed – a gas – solid reaction on an external pellet surface.

If two components take part in a surface reaction, an extra balance for the second component must be considered as well. For

$$A + \nu, B \rightarrow \text{Products}$$

obtained

$$J_A = k_{g,A} \left(\overline{C_A} - C_{A,i}\right) \tag{6.16}$$

$$J_B = k_{g,B} \left(\overline{C_B} - C_{B,i}\right) \tag{6.17}$$

If, for example, the above reaction occurs according to (1,1)-kinetics, furthermore,

$$|\mathbb{R}_A''| = k_r'' C_{A,i} C_{B,i} \tag{6.18}$$

A material balance gives

$$J_A = |\mathbb{R}_A''| \tag{6.19}$$

$$J_B = \nu J_A \tag{6.20}$$

Combining Equations (6.16) – (6.20) and eliminating $C_{A,i}$, $C_{B,i}$, and J_B give

$$J_A = k_{g,A}\overline{C_A} \cdot \frac{2\beta_B}{1+\beta_A+\beta_B+\sqrt{(1-\beta_A+\beta_B)^2+4\beta_A}}$$

$$\text{with } \beta_A = \nu\frac{k_r''\overline{C_A}}{k_{g,B}} \text{ and } \beta_B = \frac{k_r''\overline{C_B}}{k_{g,A}} \tag{6.21}$$

For the *slow reaction regime* (i.e., $\beta_A \to 0$ and $\beta_B \to 0$), Equation (6.21) simplifies to

$$J_A = k_r''\overline{C_A}\,\overline{C_B} \tag{6.22}$$

thus, the mass-transfer resistance is negligible.

For the *fast reaction regime* (i.e., $\beta_A \to \infty$ and $\beta_B \to \infty$), Equation (6.21) simplifies to one of the following equations:

1) For $\nu\, k_{g,\,A}\,\overline{C_A} < k_{g,\,B}\,\overline{C_B}$,

$$J_A = k_{g,A}\overline{C_A} \tag{6.23}$$

Hence, the overall conversion rate is limited by mass transfer of the reactant with the lowest mass-transfer rate.

2) For $\nu\, k_{g,\,A}\,\overline{C_A} > k_{g,\,B}\,\overline{C_B}$,

$$J_B = \frac{1}{\nu}k_{g,B}\overline{C_B} \tag{6.24}$$

Now B limits the overall conversion rate because it has the lowest mass-transfer rate.

Thus, corrected for stoichiometry, the key component with the lowest rate of mass transfer determines the rate of conversion, and the component in excess at the catalyst interface has no influence at all on the rate in this case.

As illustrated for monomolecular reactions, the system analyzed here is easily extended to bimolecular reactions with arbitrary kinetics by modifying the rate equation of — $\mathbb{R}_A''$ — as given in Equation (6.18), albeit the algebra involved can become quite tedious.

6.1.6. Case Study: Shrinking Core Model

As an example, a solid metal oxide is reduced with a gaseous component (e.g., hydrogen, carbon monoxide) according to the equilibrium reaction

$$A\,(g) + \nu_{MO}\,MO_x\,(s) \rightleftharpoons \nu\,P\,(g) + \nu_{MO}\,M\,(s)$$

with

$$|\mathbb{R}_A''| = k_r''\left(C_A - \frac{C_P}{K}\right) \tag{6.25}$$

where A may be H_2 or CO and P may be H_2O or CO_2, respectively; MO_x is the metal oxide (ore) and M the pure metal.

The reaction is assumed to take place at a sharp boundary between the porous metal product layer and the shrinking unreacted nonporous metal oxide core. Then the following steps are involved:

1) Diffusion of reducing gas A through the external film surrounding the pellet
2) Diffusion of A through the porous product layer of pure metal
3) Chemical reaction at the sharp interface between A and MO_x
4) Diffusion of product gas P through the porous product layer
5) Diffusion of P via the external film into the bulk of the gas

An expression can be derived for the relative degree of conversion of the metal oxide ζ_{MO} as a function of time.

The mole fluxes of components A and P at the external surface $J_{A,\,p}$ and $J_{P,\,p}$ (see Fig. 27) are

$$J_{A,\,p} = k_{g,\,A}\left(\overline{C_A} - C_{A,\,i}\right) \tag{6.26}$$

$$J_{P,\,p} = k_{g,\,P}\left(C_{P,\,i} - \overline{C_P}\right) \tag{6.27}$$

The reaction rate at the core surface — $\mathbb{R}_{A,\,c}''$ — is given by

$$|\mathbb{R}_{A,\,c}''| = k_r''\left(C_{A,\,c} - \frac{C_{P,\,c}}{K}\right) \tag{6.28}$$

From the material balances,

$$4\pi r_p^2 J_{A,\,p} = \frac{1}{\nu}4\pi r_p^2 J_{P,p} = 4\pi r_c^2\,|\mathbb{R}_{A,\,c}''| \tag{6.29}$$

From the above set of equations the quantities $J_{P,\,p}$, — $\mathbb{R}_{A,\,c}''$ —, $C_{A,\,i}$, $C_{P,\,i}$, $C_{A,\,c}$, and $C_{P,\,c}$ must be eliminated. To achieve this, $C_{A,\,c}$ must be expressed in terms of $C_{A,\,i}$, and $C_{P,\,c}$ must be expressed in terms of $C_{P,\,i}$. These expressions are obtained from material balances for A and P across an infinitesimally thin spherical slice

within the porous product layer. This is illustrated for reactant A.

Figure 27. Concentration profiles for unreacted shrinking core model, for example, with the equilibrium reaction: $MO_x + A \rightleftharpoons M + AO_x$, where MO_x = metal oxide; M = metal; and A = reducing agent (for explanation of other symbols, see text)

Since the mole flow of A through each of the infinitesimally thin slices must be the same,

$$4\pi r^2 J_A(r) = 4\pi r_p^2 J_{A,p} \neq f(r) \tag{6.30}$$

If the diffusion coefficient of A in the porous metal layer is denoted by $\mathbb{D}_{i,A}$,

$$4\pi r^2 \mathbb{D}_{i,A} \frac{\partial C_A(r)}{\partial r} = 4\pi r_p^2 J_{A,p} \tag{6.31}$$

$\mathbb{D}_{i,A}$ is discussed in more detail in the next section. The differential equation (Eq. 6.31) must be solved subject to the boundary condition:

$$r = r_p \Rightarrow C_A(r) = C_{A,i} \tag{6.32}$$

The solution is

$$C_A(r) = C_{A,i} - \frac{J_{A,p}}{\mathbb{D}_{i,A}} \frac{r_p}{r}(r_p - r) \tag{6.33}$$

By substituting $r = r_c$, $C_{A,c}$ is obtained as a function of $C_{A,i}$:

$$C_{A,c} = C_{A,i} - \frac{J_{A,p}}{\mathbb{D}_{i,A}} \frac{r_p}{r_c}(r_p - r_c) \tag{6.34}$$

Similarly, for component P,

$$C_{P,c} = C_{P,i} + \frac{J_{P,p}}{\mathbb{D}_{i,P}} \frac{r_p}{r_c}(r_p - r_c) \tag{6.35}$$

Combining Equations (6.26)–(6.29), (6.34), and (6.35) gives the mole flux of A through the external surface as a function of core and particle diameter, concentrations, and physical constants:

$$J_{A,p} = \frac{1}{\xi(\varrho)} k_{g,A} \left(\overline{C_A} - \frac{\overline{C_P}}{K} \right) \tag{6.36}$$

where $\xi(\varrho)$ can be calculated from

$$\xi(\varrho) = 2 + Bi_A \frac{1-\varrho}{\varrho} + \frac{k_{g,A}}{k_r''} \varrho^2 + \frac{\nu}{K} \frac{k_{g,A}}{k_{g,P}} Bi_P \cdot \frac{1-\varrho}{\varrho} + 2\frac{\nu}{K} \frac{k_{g,A}}{k_{g,P}} \tag{6.37}$$

Here Bi_A and Bi_P are *Biot numbers*, which are defined as follows:

$$Bi_A = \frac{k_{g,A} r_p}{\mathbb{D}_{i,A}} \tag{6.38}$$

$$Bi_P = \frac{k_{g,P} r_p}{\mathbb{D}_{i,P}} \tag{6.39}$$

ϱ is a dimensionless core radius, which can vary from 1 to 0 during the reduction process:

$$\varrho = \frac{r_c}{r_p} \tag{6.40}$$

For $\varrho = 1$, no metal oxide has been reduced and an outer porous layer is still absent. For $\varrho = 0$, all metal oxide has been reduced and a porous metal particle without an oxide core remains.

If C_{MO} is the concentration of metal oxide in the virgin particle and core region, the rate of change of core diameter $-\frac{\partial r_c(t)}{\partial t}$ is obtained from

$$4\pi r_p^2 J_{A,p}(t) = -4\pi [r_c(t)]^2 \frac{\partial r_c(t)}{\partial t} \frac{C_{MO}}{\nu_{MO}} \tag{6.41}$$

where ν_{MO} is the stoichiometric coefficient of the metal oxide as given by the chemical equation. After substitution of Equation (6.36) in Equation (6.41),

$$\frac{\partial \varrho}{\partial t} = -\frac{\nu_{MO}}{C_{MO}} \left(\overline{C_A} - \frac{\overline{C_P}}{K} \right) \frac{k_{g,A}}{r_p} \frac{1}{\varrho^2 \xi(\varrho)} \tag{6.42}$$

For constant values of $\overline{C}_A$ and $\overline{C}_P$, Equation (6.42) can be integrated for the entire process subject to the initial condition $\varrho = 1$ for $t = 0$. With the relative degree of conversion of the metal oxide following from

$$\zeta_{MO} = 1 - \varrho^3 \tag{6.43}$$

this integration yields

$$\frac{2}{3}\left(1+\frac{\nu}{K}\frac{k_{g,A}}{k_{g,P}}\right)\zeta_{MO} + \frac{1}{6}\left(Bi_A + \frac{\nu}{K}\frac{k_{g,A}}{k_{g,P}}Bi_P\right) \cdot \left[1 - 3\,(1-\zeta_{MO})^{2/3} + 2\,(1-\zeta_{MO})\right] + \frac{k_{g,A}}{k_r''}\left[1-(1-\zeta_{MO})^{1/3}\right] = \frac{\nu_{MO}}{C_{MO}}\left(\overline{C_A} - \frac{C_P}{K}\right)\frac{k_{g,A}}{r_P}t \tag{6.44}$$

Equation (6.44) is very useful in conversion experiments with a thermal balance, where $\overline{C}_A$ and $\overline{C}_P$ are kept constant. In counter- or cocurrent-flow blast furnaces or in moving-bed gasifiers, $\overline{C}_A$ and $\overline{C}_P$ vary with ζ_{MO}, so Equation (6.44) must be applied anew for each step when integrating to the reactor level in stepwise calculations.

Depending on the controlling resistance, three asymptotic cases of Equation (6.44) can be distinguished:

1) *Slow External Mass Transfer* (i.e., $\mathbb{D}_{i,A}$, $\mathbb{D}_{i,P}$, $k_r'' \to \infty$). In this regime,

$$\zeta_{MO} = \frac{t}{\tau_M} \tag{6.45}$$

with

$$\tau_M = \frac{2}{3}\left(1+\frac{\nu}{K}\right)\frac{C_{MO}}{\nu_{MO}}\left(\overline{C_A} - \frac{\overline{C_P}}{K}\right)^{-1}\frac{r_P}{k_{g,A}} \tag{6.46}$$

2) *Slow Diffusion Through Converted Shell* (i.e., $k_{g,A}$, $k_{g,P}$, $k_r'' \to \infty$). In this regime,

$$1 - 3\,(1-\zeta_{MO})^{2/3} + 2\,(1-\zeta_{MO}) = \frac{t}{\tau_D} \tag{6.47}$$

with

$$\tau_D = \frac{1}{6}\left(1+\frac{\nu}{K}\frac{\mathbb{D}_{i,A}}{\mathbb{D}_{i,P}}\right)\frac{C_{MO}}{\nu_{MO}}\left(\overline{C_A} - \frac{\overline{C_P}}{K}\right)^{-1}\frac{r_P^2}{\mathbb{D}_{i,P}} \tag{6.48}$$

3) *Slow Chemical Reaction Kinetics* (i.e., $k_{g,A}$, $k_{g,P}$, $\mathbb{D}_{i,A}$, $\mathbb{D}_{i,P} \to \infty$). In this regime,

$$1 - (1-\zeta_{MO})^{1/3} = \frac{t}{\tau_R} \tag{6.49}$$

with

$$\tau_R = \frac{C_{MO}}{\nu_{MO}}\left(\overline{C_A} - \frac{\overline{C_P}}{K}\right)^{-1}\frac{r_P}{k_r''} \tag{6.50}$$

Figure 28 shows $\frac{\partial \zeta_{MO}}{\partial (t/\tau)}$ (with $\tau = \tau_M, \tau_D, \tau_R$) as a function of ζ_{MO} for the various asymptotic solutions. Notice that in practice the rate-controlling step may depend on the value of ζ_{MO}. For low conversions, diffusion through the porous metal layer is not necessary and external mass transfer or reaction will control the overall conversion rate. For large conversions and not too small particles, diffusion through the porous layer often controls the rate of conversion.

Figure 28. Conversion rate as a function of conversion according to the shrinking core model
a) External mass transfer in gas controls ($\tau = \tau_M$); b) Diffusion in converted shell controls ($\tau = \tau_D$); c) Chemical reaction rate controls ($\tau = \tau_R$)

6.1.7. Selectivities of Multiple Reactions

6.1.7.1. Introduction

Up to now, mass transfer and reaction in series have been described with one reaction only. More often than not, a reactant is involved in at least two reactions. Generally, only one of the

products is commercially desirable and the reactions must be carried out so that both an acceptable conversion and acceptable selectivity are obtained. Therefore, this section deals with the problem of selectivity for multiphase reactions and with mass transfer and reaction in series.

A distinction is made between *parallel* and *consecutive reactions* [30]:

respectively,

Combinations of both are also possible; in oxidation reactions the following scheme is often encountered:

where A is the reactant (e.g., ethylene), P a desired product obtained after partial oxidation (ethylene oxide), and X the byproducts obtained after complete combustion (carbon dioxide, water).

6.1.7.2. Parallel Reactions

For the following reaction scheme

the desired product P is assumed to be formed with a reaction rate $-\mathbb{R}''_A(C_A)-_P$, whereas for the undesired product X the rate equals $-\mathbb{R}''_A(C_A)-_X$. The selectivity toward the desired product P then follows from (see Eq. 2.8)

$$\sigma_P = \frac{|\mathbb{R}''_A(C_{A,i})|_P}{|\mathbb{R}''_A(C_{A,i})|_P + |\mathbb{R}''_A(C_{A,i})|_X} \tag{6.51}$$

where σ_P can vary between 0 and 1.

For n-th and m-th-order kinetics

$$|\mathbb{R}''_A(C_A)|_P = k''_P C_A^n \tag{6.52}$$

$$|\mathbb{R}''_A(C_A)|_X = k''_X C_A^m \tag{6.53}$$

Equation (6.51) yields

$$\sigma_P = \left(1 + \frac{k''_X}{k''_P} C_{A,i}^{m-n}\right)^{-1} \tag{6.54}$$

If the desired reaction is of higher order ($n > m$), a high $C_{A,i}$ (thus high $\overline{C}_A$ and high k_g) will favor the selectivity. The high k_g requires small particles and a relatively high fluid velocity. For the special case in which the parallel reactions are of the same order (i.e., $n = m$), the selectivity is not influenced by mass-transfer limitation and

$$\sigma_P = \frac{k''_P}{k''_P + k''_X} \tag{6.55}$$

However, for this situation the relative degree of conversion ζ_A may still depend on the rate of mass transfer.

In general, selectivity can be influenced by mass-transfer limitation, as is the case for $n \neq m$. For such cases the concentration $C_{A,i}$ is needed to calculate the selectivity (e.g., see Eq. 6.54). The parameter $C_{A,i}$ follows from a mass balance for A:

$$J_A = k_g(\overline{C_A} - C_{A,i}) = |\mathbb{R}''_A(C_{A,i})|_P + |\mathbb{R}''_A(C_{A,i}|_X) \tag{6.56}$$

Solving the above equation, expressing $C_{A,i}$ in $\overline{C}_A$, and substituting this relation in Equation (6.51), gives a straightforward expression for σ_P in $\overline{C}_A$. Thus, for $n = 2$ and $m = 1$, Equation (6.56) yields

$$C_{A,i} = \overline{C_A} \frac{2}{1 + \beta_X + \sqrt{(1+\beta_X)^2 + 4\beta_P}}$$

$$\beta_P = \frac{k''_P}{k_g} \quad \text{and} \quad \beta_X = \frac{k''_X}{k_g} \tag{6.57}$$

which, upon substitution in Equation (6.54), gives

$$\sigma_P = \left\{1 + \frac{\beta_X}{2\beta_P}\left[1 + \beta_X + \sqrt{(1+\beta_X)^2 + 4\beta_P}\right]\right\}^{-1} \tag{6.58}$$

with β_P and β_X as in Equation (6.57). Since the desired reaction is of higher order ($n > m$), a high k_g yields the highest selectivity. This selectivity is found by substituting β_P and $\beta_X \to 0$ in Equation (6.58), which yields

$$\sigma_{\mathrm{P,max}} = \frac{k''_{\mathrm{P}}\,\overline{C_{\mathrm{A}}}}{k''_{\mathrm{P}}\,\overline{C_{\mathrm{A}}} + k''_{\mathrm{X}}} \tag{6.59}$$

This is the selectivity for slow reaction or no mass-transfer limitation at all.

For very low k_{g} values (i.e., in the fast reaction regime), the lowest selectivity is obtained. An expression is obtained by substituting β_{P} and $\beta_{\mathrm{X}} \to \infty$ in Equation (6.58), which yields

$$\sigma_{\mathrm{P,min}} = \frac{k_{\mathrm{g}} k''_{\mathrm{P}}\,\overline{C_{\mathrm{A}}}}{\left(k''_{\mathrm{X}}\right)^2} \tag{6.60}$$

Hence, in the fast reaction regime, selectivity is proportional to the mass-transfer coefficient k_{g}, which illustrates the importance of achieving as high a mass-transfer coefficient as possible. Expressions for σ_{P} for other forms of kinetics are obtained in a similar way as illustrated above.

6.1.7.3. Consecutive Reactions

The following reaction scheme is considered:

$$\mathrm{A} \xrightarrow{k''_{\mathrm{P}}} \nu_{\mathrm{P}}\mathrm{P} \xrightarrow{k''_{\mathrm{X}}} \nu_{\mathrm{X}}\mathrm{X}$$

The reaction of A to form the desired product P is assumed to have a rate — $\mathbb{R}''_{\mathrm{A}}\left(C_{\mathrm{A}}\right)$ — in moles of A per square meter per second; the rate of the reaction of P forming the undesired product X equals — $\mathbb{R}''_{\mathrm{P}}\left(C_{\mathrm{P}}\right)$ — in moles of P per square meter per second. The selectivity toward the desired product P then follows from (see Eq. 2.8)

$$\sigma_{\mathrm{P}} = \frac{\nu_{\mathrm{P}}\left|\mathbb{R}''_{\mathrm{A}}\left(C_{\mathrm{A,i}}\right)\right| - \left|\mathbb{R}''_{\mathrm{P}}\left(C_{\mathrm{P,i}}\right)\right|}{\nu_{\mathrm{P}}\left|\mathbb{R}''_{\mathrm{A}}\left(C_{\mathrm{A,i}}\right)\right|} \tag{6.61}$$

σ_{P} is always less than unity. It need not, however, be larger than 0: for — $\mathbb{R}''_{\mathrm{P}}\left(C_{\mathrm{P,i}}\right)$ — $> \nu_{\mathrm{P}}$ — $\mathbb{R}''_{\mathrm{A}}\left(C_{\mathrm{A,i}}\right)$ —, more P is converted to X than formed from A. Hence, a net overall consumption of P occurs, which results in a negative value for σ_{P}.

The interface concentrations $C_{\mathrm{A,i}}$ and $C_{\mathrm{P,i}}$ are again obtained from mass balances:

$$J_{\mathrm{A}} = k_{\mathrm{g,A}}\left(\overline{C_{\mathrm{A}}} - C_{\mathrm{A,i}}\right) = \left|\mathbb{R}''_{\mathrm{A}}\left(C_{\mathrm{A,i}}\right)\right| \tag{6.62}$$

$$\begin{aligned} J_{\mathrm{P}} &= k_{\mathrm{g,P}}\left(C_{\mathrm{P,i}} - \overline{C_{\mathrm{P}}}\right) \\ &= \nu_{\mathrm{P}}\left|\mathbb{R}''_{\mathrm{A}}\left(C_{\mathrm{A,i}}\right)\right| - \left|\mathbb{R}''_{\mathrm{P}}\left(C_{\mathrm{P,i}}\right)\right| \end{aligned} \tag{6.63}$$

With the above set of equations, $C_{\mathrm{A,i}}$ and $C_{\mathrm{P,i}}$ can be expressed in the bulk concentrations $\overline{C_{\mathrm{A}}}$ and $\overline{C_{\mathrm{P}}}$, which upon substitution in Equation (6.61) give σ_{P} as a function of bulk concentration.

For cases in which both reactions are *first order*,

$$\left|\mathbb{R}''_{\mathrm{A}}\left(C_{\mathrm{A}}\right)\right| = k''_{\mathrm{P}} C_{\mathrm{A}} \tag{6.64}$$

$$\left|\mathbb{R}''_{P}\left(C_{\mathrm{P}}\right)\right| = k''_{\mathrm{X}} C_{\mathrm{P}} \tag{6.65}$$

Combining Equations (6.61) – (6.65) gives

$$\sigma_{\mathrm{P}} = \frac{1 - \Sigma\left(1 + \beta_{\mathrm{A}}\right)}{1 + \beta_{\mathrm{P}}}$$

$$\Sigma = \frac{1}{\nu_{\mathrm{P}}}\frac{k''_{\mathrm{X}}}{k''_{\mathrm{P}}}\frac{\overline{C_{\mathrm{P}}}}{\overline{C_{\mathrm{A}}}}, \quad \beta_{\mathrm{A}} = \frac{k''_{\mathrm{P}}}{k_{\mathrm{g,A}}}, \quad \beta_{\mathrm{P}} = \frac{k''_{\mathrm{X}}}{k_{\mathrm{g,P}}} \tag{6.66}$$

Two asymptotic solutions can be distinguished:

1) *Slow Reaction Regime*. Here β_{A} and $\beta_{\mathrm{P}} \to 0$; hence,

$$\sigma_{\mathrm{P}} = 1 - \Sigma = 1 - \frac{1}{\nu_{\mathrm{P}}}\frac{k''_{\mathrm{X}}}{k''_{\mathrm{P}}}\frac{\overline{C_{\mathrm{P}}}}{\overline{C_{\mathrm{A}}}} \tag{6.67}$$

which is the solution for no mass-transfer limitation at all.

2) *Fast Reaction Regime*. Here β_{A} and $\beta_{\mathrm{P}} \to \infty$, hence,

$$\sigma_{\mathrm{P}} = -\Sigma\frac{\beta_{\mathrm{A}}}{\beta_{\mathrm{P}}} = -\frac{1}{\nu_{\mathrm{P}}}\frac{k_{\mathrm{g,P}}}{k_{\mathrm{g,A}}}\frac{\overline{C_{\mathrm{P}}}}{\overline{C_{\mathrm{A}}}} \tag{6.68}$$

Thus, in this regime the reaction rate constants do not influence selectivity. Furthermore, as soon as some P has been produced and is present in the bulk, the selectivity is always negative. This situation, of course, must always be prevented if P is the desired product.

The selectivity, in terms of "near surface" concentrations, is (see Eq. 6.61)

$$\sigma_{\mathrm{P}} = 1 - \frac{1}{\nu_{\mathrm{P}}}\frac{k''_{\mathrm{X}}}{k''_{\mathrm{P}}}\frac{C_{\mathrm{P,i}}}{C_{\mathrm{A,i}}} =$$

$$1 - \frac{1}{\nu_{\mathrm{P}}}\frac{k''_{\mathrm{X}}}{k''_{\mathrm{P}}}\frac{\overline{C_{\mathrm{P}}}}{\overline{C_{\mathrm{A}}}} \times \frac{\overline{C_{\mathrm{A}}}}{C_{\mathrm{A,i}}}\frac{C_{\mathrm{P,i}}}{\overline{C_{\mathrm{P}}}} \tag{6.69}$$

Due to mass-transfer limitation, the term $\frac{\overline{C_{\mathrm{A}}}}{C_{\mathrm{A,i}}}\frac{C_{\mathrm{P,i}}}{\overline{C_{\mathrm{P}}}}$ may increase from unity (slow reaction regime) to infinity (fast reaction

regime). Hence, selectivity decreases tremendously with increasing mass-transfer limitation. Consequently, mass-transfer limitations must be avoided with heterogeneous consecutive reactions $A \longrightarrow P \longrightarrow X$. Therefore, a temperature increase sufficient to enhance the reaction rates always spoils the selectivity, even if both reactions have equal activation energies, because reaction rates usually increase much faster with temperature than mass-transfer rates.

Figure 29. Selectivity σ_P as a function of k''_P/k_g for mass transfer and reaction in series with consecutive first-order reactions $A \longrightarrow P \longrightarrow X$ under the assumption that $k_{g,A} = k_{g,P} = k_g$ and $k''_X/k''_P = 1$
Several values of $\overline{C_P}/\overline{C_A}$ have been substituted.

Some other aspects are noteworthy. If no mass-transfer limitations occur, selectivity for the condition $\overline{C_P} = 0$ (e.g., initial selectivity at the reactor inlet) always equals 1, since $-\mathbb{R}''_P(\overline{C_P})- = 0$ because of the absence of P. When mass transfer is significant, this is no longer true. From Equation (6.66), for $\overline{C_P} = 0$ (i.e., $\Sigma = 0$),

$$\sigma_P = \left(1 + \frac{k''_X}{k_{g,P}}\right)^{-1} \tag{6.70}$$

which is only 1 for $k''_X/k_{g,P} << 1$ (i.e., in the slow reaction regime). Again, the reason for this decrease in selectivity is accumulation of P at the interface.

In general, the selectivity σ_P depends strongly on k''_X/k_g. Figure 29 shows how selectivity decreases dramatically with this ratio for a fixed value of k''_X/k''_P, several values of $\overline{C_P}/\overline{C_A}$, and $k_g = k_{g,A} = k_{g,P}$. For low ratios of k''_X/k_g, selectivities are very high due to the selected value of $k''_X/k''_P = 0.1$. With increasing k''_X/k_g, on entering the region of mass-transfer limitation, σ_P decreases rapidly to become constant again roughly for $k''_X/k_g \approx 10^3$. In the latter case the reactions are completely mass-transfer limited; hence σ_P becomes independent of the reaction rate constants and also of the ratio k''_X/k_g. Notice, the occurrence of negative values for σ_P, indicating a net consumption of P.

6.1.7.4. Complex Reaction Schemes

For more complex reaction schemes, selectivity calculations for mass transfer and reaction in series are always as straightforward as discussed above. An illustration for the following scheme is given:

where all three reactions are assumed to be first order. The rates $k''_{AP}\,C_A$, $k''_{AX}\,C_A$, and $k''_{PX}C_P$ have the dimensions mol m^{-2} s^{-1}.

For this scheme the selectivity is found as

$$\sigma_P = \frac{\nu_P k''_{AP} C_{A,i} - k''_{PX} C_{P,i}}{\nu_P k''_{AP} C_{A,i} + \nu_P k''_{AX} C_{A,i}} \tag{6.71}$$

σ_P is always smaller than unity and can again become negative, indicating a net consumption of P.

The interface concentrations follow from the mass balance for A and P:

$$J_A = k_{g,A}\left(\overline{C_A} - C_{A,i}\right) = k''_{AP} C_{A,i} + k''_{AX} C_{A,i} \tag{6.72}$$

$$J_P = k_{g,P}\left(C_{P,i} - \overline{C_P}\right) = \nu_P k''_{AP} C_{A,i} - k''_{PX} C_{P,i} \tag{6.73}$$

Combining Equations (6.71) – (6.73) gives the following expression for selectivity:

$$\sigma_{\mathrm{P}} = \frac{1}{1+\Sigma_{\mathrm{p}}} \cdot \frac{1-\Sigma_{\mathrm{c}}\,(1+\beta_{\mathrm{A}})}{1+\beta_{\mathrm{P}}}$$

$$\Sigma_{\mathrm{p}} = \frac{k''_{\mathrm{AX}}}{k''_{\mathrm{AP}}}\,,\ \Sigma_{\mathrm{c}} = \frac{1}{\nu_{\mathrm{P}}}\,\frac{k''_{\mathrm{PX}}}{k''_{\mathrm{AP}}}\,\frac{\overline{C_{\mathrm{P}}}}{\overline{C_{\mathrm{A}}}}$$

$$\beta_{\mathrm{A}} = \frac{k''_{\mathrm{AP}}+k''_{\mathrm{AX}}}{k_{\mathrm{g,\,A}}}\,,\ \beta_{\mathrm{P}} = \frac{k''_{\mathrm{X}}}{k_{\mathrm{g,\,P}}} \tag{6.74}$$

Notice the resemblance between Equations (6.66) and (6.74). For the above reaction scheme, conclusions similar to those in the previous sections can be drawn. The only point highlighted here is that in the fast reaction regime (i.e., β_{A} and $\beta_{\mathrm{P}} \to \infty$),

$$\sigma_{\mathrm{P}} = -\frac{1}{\nu_{\mathrm{P}}}\,\frac{k_{\mathrm{g,\,P}}}{k_{\mathrm{g,\,A}}}\,\frac{\overline{C_{\mathrm{P}}}}{\overline{C_{\mathrm{A}}}}\,\frac{k''_{\mathrm{AP}}}{k''_{\mathrm{AP}}+k''_{\mathrm{AX}}} \tag{6.75}$$

hence, the reaction scheme discussed here differs from a purely consecutive reaction insofar as, in the fast reaction regime, selectivity is still a function of the kinetic constants.

6.2. Mass Transfer with Simultaneous Reaction

6.2.1. Introduction

The analysis in Section 6.1 did not require the Higbie penetration, surface renewal, or stagnant film models: values of the mass-transfer coefficients alone were sufficient. If mass transfer and reaction occur simultaneously, the distinction between the models can become significant. Simultaneous mass transfer and reaction mean:

1) For the Higbie penetration and surface renewal models: During the contact time of the element, mass transfer and reaction within the element interact.
2) For the stagnant film model: Mass transfer and reaction within the film exhibit interaction. Consequently, the concentration profile in the film need not be a straight line as was the case for mass transfer without reaction.

In this section, two general situations are discussed:

1) Reaction with diffusion of gases in a porous catalyst, where gaseous components react on the internal catalyst surface. This situation generally occurs in heterogeneous catalysis. For this application, either an interface covered with small stagnant fluid elements or a stagnant film with negligible curvature somewhere inside the pellet is difficult to imagine. Therefore the penetration and film models are less applicable here. Consequently, calculations for this type of problem are usually based on basic mass balances instead (e.g., Eq. 5.6).
2) Reaction with mass transfer in a liquid phase, where the reactant or at least one of the reactants is absorbed from a gas phase that is in contact with the liquid. Here the penetration and film models appear and are readily applicable, as can be illustrated.

In this section, mass transfer and reaction are assumed to occur simultaneously; the phenomenon of mass transfer and reaction in series is not considered:

1) For simultaneous reaction and diffusion of gases in a porous solid, mass-transfer resistance outside the solid is assumed to be infinitely small, so it need not be considered
2) For simultaneous reaction and mass transfer of gases in the liquid, mass transfer on the gas-phase side of the gas – liquid interface is assumed to be infinitely fast, so it need not be taken into account

The coupling of simultaneous and series mass transfer and reaction is discussed in Section 6.3.

6.2.2. Reaction of Gases in Porous Solids

6.2.2.1. Introduction

For the above situation the conversion is determined mainly by the following:

Microkinetic Scale. Conversion depends on

1) *Reaction properties*, such as the reaction kinetics, the number of reactants involved, and the complexity of the reaction scheme under consideration
2) *Catalyst pellet microproperties*, such as the pore-size distribution and tortuosity of the pores
3) *Physical properties*, such as the diffusion rates of the reacting components in the fluid phase and under Knudsen flow

Macrokinetic Scale. Conversion depends on the *catalyst pellet macroproperties*, such as the size and shape of the pellet and the possible occurrence of pellet anisotropy.

The microproperties of the catalyst pellet cannot be determined easily. Moreover, their interaction with the physical properties of the components is rather complex. Therefore, models that take microproperties into account tend to be very complex and inaccurate (e.g., [31]). Consequently, the microproperties of the catalyst and the physical properties of the components are usually accounted for by a lumped parameter, the so-called *effective diffusion coefficient* $\mathbb{D}_{\mathrm{i}}$. An often-used approximation for $\mathbb{D}_{\mathrm{i}}$ is

$$\mathbb{D}_{\mathrm{i}} = \frac{\varepsilon_{\mathrm{p}}}{\gamma_{\mathrm{p}}} \left(\frac{1}{\mathbb{D}_{\mathrm{fl}}} + \frac{1}{\mathbb{D}_{\mathrm{Kn}}} \right)^{-1} \tag{6.76}$$

with ε_{p} the particle porosity, γ_{p} the tortuosity of the particle pores, $\mathbb{D}_{\mathrm{fl}}$ the molecular diffusion coefficient of the component in the fluid (m^2/s), and $\mathbb{D}_{\mathrm{Kn}}$ its Knudsen diffusion coefficient (m^2/s), which is the diffusion coefficient found if the mean free path of the molecules is much larger than the average pore diameter of the particle. This is relevant only for a gas, since the mean free path of the molecules for liquids is on the order of the molecular dimensions and, hence, always much smaller than the pore diameter. Equation (6.76) is not applicable if the surface migration (sometimes called surface diffusion) of the component plays a role.

Using $\mathbb{D}_{\mathrm{i}}$ as lumping parameter for solid catalyst particles has proven useful, provided the particles can be regarded as being homogeneous on a microscale. However, if this is not the case (e.g., for zeolites in an amorphous matrix), care should be taken in using this approach [32], [33].

The concept of an effective diffusion coefficient is assumed not to introduce too large an error. Hence, the effect of catalyst microproperties and physical properties of the components are not examined here, and the value of $\mathbb{D}_{\mathrm{i}}$ is assumed to be known.

6.2.2.2. Monomolecular First-Order Kinetics

Assume that a simple reaction $\mathrm{A} \longrightarrow \nu_{\mathrm{P}}\ \mathrm{P}$ is carried out in a spherical, porous catalyst pellet with a radius r_{p}. A mass balance for an infinitesimally thin, spherical slice within the particle yields (compare with Eq. 5.6):

$$\mathbb{D}_{\mathrm{i,\,A}} \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial C_{\mathrm{A}}}{\partial r} \right) = |\mathbb{R}_{\mathrm{A}}|_{\mathrm{p}} \tag{6.77}$$

where the coordinate r is zero in the sphere center and $r = r_{\mathrm{p}}$ at the outer surface; $-\!\!-\mathbb{R}_{\mathrm{A}}-\!\!-_{\mathrm{p}}$ is the chemical reaction rate in moles of A per cubic meter of catalyst particle volume per second, as used before. This rate is not the same as the rate $-\!\!-\mathbb{R}_{\mathrm{A}}-\!\!-_{\mathrm{r}}$ in moles of A per cubic meter of reactor volume per second. If $1-\varepsilon$ is the volume holdup of porous catalyst material in a reactor (i.e., ε is the porosity or void fraction), the two rates are related according to

$$|\mathbb{R}_{\mathrm{A}}|_{\mathrm{r}} = (1-\varepsilon)\ |\mathbb{R}_{\mathrm{A}}|_{\mathrm{p}} \tag{6.78}$$

To calculate the concentration profile inside the spherical particle, Equation (6.77) must be solved subject to the following boundary conditions:

$$r = 0 \Rightarrow C_{\mathrm{A}} \text{ is bounded} \tag{6.79}$$

$$r = r_{\mathrm{p}} \Rightarrow C_{\mathrm{A}} = C_{\mathrm{A,\,i}} \tag{6.80}$$

here $C_{\mathrm{A,\,i}}$ is the concentration of A in the gas at the interface with the pellet. For first-order kinetics, i.e.,

$$|\mathbb{R}_{\mathrm{A}}|_{\mathrm{p}} = k_{\mathrm{p}} C_{\mathrm{A}} \tag{6.81}$$

solution of the differential equation gives

$$\frac{C_{\mathrm{A}}}{C_{\mathrm{A,i}}} = \frac{r_{\mathrm{p}}}{r} \frac{\sinh\left(\varphi_{\mathrm{T}} \frac{r}{r_{\mathrm{p}}}\right)}{\sinh\left(\varphi_{\mathrm{T}}\right)} \tag{6.82}$$

with φ_{T} the *Thiele modulus* defined as

$$\varphi_{\mathrm{T}} = r_{\mathrm{p}} \sqrt{\frac{k_{\mathrm{p}}}{\mathbb{D}_{\mathrm{i,\,A}}}} \tag{6.83}$$

The conversion rate of A for one pellet can be calculated from

$$\begin{aligned} 4\pi r_{\mathrm{p}}^2 J_{\mathrm{A,\,p}} &= 4\pi r_{\mathrm{p}}^2 \mathbb{D}_{\mathrm{i,\,A}} \frac{\partial C_{\mathrm{A}}(r)}{\partial r}\Big|_{r=r_{\mathrm{p}}} \\ &= 4\pi r_{\mathrm{p}} \mathbb{D}_{\mathrm{i,\,A}} C_{\mathrm{A,\,i}} \left(\frac{\varphi_{\mathrm{T}}}{\tanh\left(\varphi_{\mathrm{T}}\right)} - 1 \right) \end{aligned} \tag{6.84}$$

Use of the *effectiveness factor* is convenient. THIELE was one of the first to use this concept [34]. He defined the effectiveness factor as the

amount of a key reactant that is actually converted, divided by the amount that could have been converted if no retardation by diffusion had occurred. In this case the amount of A converted would equal $4/3\,\pi\, r_p^3\, k_p\, C_{A,i}$ (moles of A per m^3 pellet per unit time); hence, the effectiveness factor η is

$$\eta = \frac{3}{\varphi_T}\left(\frac{1}{\tanh(\varphi_T)} - \frac{1}{\varphi_T}\right) \tag{6.85}$$

In a similar way, equations are derived for other catalyst geometries. That is for an infinitely long cylinder with a radius r_p, Equation (6.77) must be replaced by

$$\mathbb{D}_{i,A}\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial C_A}{\partial r}\right) = |\mathbb{R}_A|_p \tag{6.86}$$

Again assuming first-order kinetics and going through the same routine as discussed above gives

$$\eta = 2\,\frac{I_1(\varphi_T)}{\varphi_T\, I_0(\varphi_T)} \tag{6.87}$$

with φ_T as given by Equation (6.83), and I_0 and I_1 being modified Bessel functions of the first kind of zeroth and first order, respectively.

For an infinitely large slab with r_p half the thickness of the slab, finally, Equation (6.77) must be replaced by

$$\mathbb{D}_{i,A}\frac{\partial^2 C_A}{\partial r^2} = |\mathbb{R}_A|_p \tag{6.88}$$

which, if first-order kinetics are assumed, can be shown to yield

$$\eta = \frac{\tanh(\varphi_T)}{\varphi_T} \tag{6.89}$$

Figure 30. Effectiveness factor η versus "simple" Thiele modulus φ_T (not shape generalized) for first-order kinetics and the following catalyst particle geometries
a) Infinite slab; b) Infinite cylinder; c) Sphere

Equations (6.85), (6.87), and (6.89) are illustrated in Figure 30, where the effectiveness factor η is plotted versus the Thiele modulus φ_T for all three geometries discussed. As the Thiele modulus increases, the reaction becomes more limited by diffusion and thus the effectiveness factor decreases. For very low values of the Thiele modulus the effectiveness factor is unity; for very high values it is inversely proportional to the Thiele modulus.

The Thiele modulus may be regarded as a measure of the ratio of the reaction rate to the rate of diffusion. However, many different definitions are used in the literature. The best definition is a general one, which allows direct comparison of the Thiele moduli for arbitrary catalyst geometries. This definition is discussed below.

Aris was the first who noticed that all $\eta - \varphi_T$ curves can be brought together in the low η region if, instead of r_p, the characteristic dimension V_p/A_p is used, where V_p is the pellet volume and A_p the external surface area of the pellet [35]. Thus he defined the *shape-generalized Thiele modulus* for first-order kinetics as

$$\varphi_A = \frac{V_p}{A_p}\sqrt{\frac{k_p}{\mathbb{D}_{i,A}}} \tag{6.90}$$

In Figure 31, η is plotted versus φ_A for the three geometries discussed. The curves coincide in both the high and the low η region. In the intermediate region the spread among the curves is largest, but still limited.

Figure 31. Effectiveness factor η versus the Aris shape-generalized Thiele modulus φ_A for first-order kinetics and the following catalyst particle geometries
a) Infinite slab; b) Infinite cylinder; c) Sphere

With the aid of the Aris' shape-generalized Thiele modulus, general statements on the possible regimes can be made that are met in reactions with internal diffusion:

Slow Reaction Regime ($\varphi_A < 0.2$). The effectiveness factor can be assumed to be unity, and mass transfer inside the pellet by diffusion is so fast that it can be neglected.

Fast Reaction Regime ($\varphi_A > 2$). Internal mass transfer by diffusion is significant. In this regime the conversion rate $-R_A-_p$ is linked to the reaction rate $-\mathbb{R}_A-_p$ as

$$|R_A|_p = \eta |\mathbb{R}_A|_p = \frac{|\mathbb{R}_A|_p}{\varphi_A} \tag{6.91}$$

Equation (6.91) implies for first-order kinetics that the apparent rate or conversion rate to be observed in the fast reaction regime equals

$$|R_A|_p = \frac{A_p}{V_p}\sqrt{k_p \mathbb{D}_{i,A}}\, C_{A,i} \tag{6.92}$$

which is different from the reaction rate that would be found if no diffusion limitation occurred:

$$|\mathbb{R}_A|_p = k_p C_{A,i} \tag{6.93}$$

Consequently, for $\varphi_A > 2$, the conversion is a strong function of catalyst particle diameter. Also the apparent activation energy of the reaction is only half of the true activation energy, since the internal diffusion coefficient is almost independent of temperature compared to the rate constant k_p.

The power of the Aris shape-generalized Thiele modulus can be illustrated further by using a ring-shaped catalyst or Raschig ring as an example (see Fig. 32). For this geometry the shape-generalized Thiele modulus is found to be

$$\varphi_A = \frac{1}{2}\left(\frac{1}{\lambda} + \frac{1}{1-\iota}\right)^{-1} R_u \sqrt{\frac{k_p}{\mathbb{D}_{i,A}}} \tag{6.94}$$

with

$$\lambda = \frac{H}{R_u} \tag{6.95}$$

and

$$\iota = \frac{R_i}{R_u} \tag{6.96}$$

Now the mass balance (Eq. 5.6) reduces to

$$\mathbb{D}_{i,A}\left[\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial C_A}{\partial r}\right) + \frac{\partial^2 C_A}{\partial h^2}\right] = |\mathbb{R}_A|_p \tag{6.97}$$

which can be solved subject to the boundary conditions

$$r = R_i \Rightarrow C_A = C_{A,i} \tag{6.98}$$

$$r = R_u \Rightarrow C_A = C_{A,i} \tag{6.99}$$

$$h = 0 \Rightarrow C_A = C_{A,i} \tag{6.100}$$

$$h = H \Rightarrow C_A = C_{A,i} \tag{6.101}$$

Calculating the effectiveness factor as illustrated above gives

$$\eta = 1 - \frac{32}{\pi^2}\cdot\frac{\varphi_A^2}{1-\iota^2}\left(\frac{1}{\lambda} + \frac{1}{1-\iota}\right)^2 \cdot \sum_{m=1}^{\infty}\frac{1-\iota^2 - 2f(\iota,\alpha_m)}{(2m+1)^2\alpha_m^2} \tag{6.102}$$

with

$$\alpha_m = \sqrt{\left[\frac{(2m+1)\pi}{\lambda}\right]^2 + \left[2 + \left(\frac{1}{\lambda} + \frac{1}{1-\iota}\right)\varphi_A\right]^2} \tag{6.103}$$

$$f(x,y) = \frac{2 - y\,Q_0(xy,y) - xy\,Q_0(y,xy)}{y^2 P_0(xy,y)} \tag{6.104}$$

$$Q_0(x,y) = I_0(x)K_1(y) + I_1(y)K_0(x) \tag{6.105}$$

$$P_0(x,y) = I_0(x)K_0(y) - I_0(y)K_0(x) \tag{6.106}$$

where I_n and K_n are n-th-order modified Bessel functions of the first and second kind, respectively. Hence, for relatively simple catalyst geometries and reaction kinetics, the mathematics can be quite involved and the resulting formulas can become quite complex and tedious. For this reason the effectiveness factor is often approximated by the following relation:

$$\eta = \frac{\tanh(\varphi_A)}{\varphi_A} \tag{6.107}$$

Alternatively, the following approximation is sometimes used:

$$\eta = \frac{1}{\sqrt{1+\varphi_A^2}} \tag{6.108}$$

The above approximations can be used only if the shape-generalized Thiele modulus is employed. Both approximations are almost exact in the regimes $\varphi_A < 0.2$ and $\varphi_A > 2$. The largest error is found in the intermediate region and can be expected to be at most roughly 10 % for first-order reactions.

Figure 32. Microscale mass balance for catalyst pellet with the shape of a Raschig ring

6.2.2.3. Monomolecular Arbitrary Kinetics

Like the shape generalization of the Thiele modulus suggested by ARIS [35], a generalization for reaction kinetics can be made. This was introduced by BISCHOFF [36]. If the effective diffusion coefficient is independent of the concentration of A, for a Thiele modulus defined as

$$\varphi = \frac{V_\mathrm{p}}{A_\mathrm{p}} \left| \mathbb{R}_\mathrm{A} \left(C_\mathrm{A,i} \right) \right|_\mathrm{p} \cdot \left(2\mathbb{D}_\mathrm{i,A} \int_0^{C_\mathrm{A,i}} \left| \mathbb{R}_\mathrm{A} \left(C_\mathrm{A} \right) \right|_\mathrm{p} \partial C_\mathrm{A} \right)^{-\frac{1}{2}} \tag{6.109}$$

in the low η region

$$\left| \mathbb{R}_\mathrm{A} \right|_\mathrm{p} = \frac{\left| \mathbb{R}_\mathrm{A} \right|_\mathrm{p}}{\varphi} \tag{6.110}$$

Hence, again in the low η region, all $\eta - \varphi$ curves are brought together, with this Thiele modulus for both arbitrary catalyst geometries and arbitrary kinetics. In what follows the Thiele modulus defined according to Equation (6.110) is used.

For *simple n-th-order kinetics*, i.e.,

$$\left| \mathbb{R}_\mathrm{A} \right|_\mathrm{p} = k_\mathrm{p} C_\mathrm{A}^n \tag{6.111}$$

Equation (6.109) yields

$$\varphi = \frac{V_\mathrm{p}}{A_\mathrm{p}} \sqrt{\frac{n+1}{2} \frac{k_\mathrm{p} C_\mathrm{A,i}^{n-1}}{\mathbb{D}_\mathrm{i,A}}} \tag{6.112}$$

which for $n = 1$ reduces to the shape-generalized Thiele modulus of Aris for first-order kinetics (Eq. 6.90):

$$\varphi = \varphi_\mathrm{A} = \frac{V_\mathrm{p}}{A_\mathrm{p}} \sqrt{\frac{k_\mathrm{p}}{\mathbb{D}_\mathrm{i,A}}} \tag{6.113}$$

As a second illustration, for *Langmuir kinetics*,

$$\left| \mathbb{R}_\mathrm{A} \right|_\mathrm{p} = \frac{k_\mathrm{p} C_\mathrm{A}}{1 + K C_\mathrm{A}} \tag{6.114}$$

and it is found that

$$\varphi = \frac{V_\mathrm{p}}{A_\mathrm{p}} \frac{K C_\mathrm{A,i}}{1 + K C_\mathrm{A,i}} \cdot \sqrt{\frac{k_\mathrm{p}}{2\mathbb{D}_\mathrm{i,A} \left[K C_\mathrm{A,i} - \ln \left(1 + K C_\mathrm{A,i} \right) \right]}} \tag{6.115}$$

For other kinetics, similar equations can readily be derived.

The mathematics necessary to derive the exact equations for η can be quite involved even for first-order kinetics. For arbitrary kinetics the problem is still worse: for most forms of kinetics, for example, Equations (6.77), (6.86), (6.88), and (6.97) cannot be solved analytically, so numerical techniques must be used. This explains why, for arbitrary kinetics, more often than not, approximations are used. The most popular approximations are similar to Equations (6.107) and (6.108):

$$\eta = \frac{\tanh(\varphi)}{\varphi} \tag{6.116}$$

or

$$\eta = \frac{1}{\sqrt{1 + \varphi^2}} \tag{6.117}$$

However, the error introduced by using one of the above approximations can be quite substantial. In general, it becomes larger for lower (apparent) reaction orders. Therefore, use of the

above approximations for (apparent) reaction orders below zero is not recommended without further studies. Only in the low η regime, where $\eta = 1\varphi$ is valid, are Equations (6.116) and (6.117) trustworthy. For (apparent) reaction orders above zero the equations give a fair indication, and maximum errors up to roughly 20 % must be expected in the intermediate region.

6.2.2.4. Bimolecular Reactions

For bimolecular reactions of the type

$$\mathrm{A} + \nu\,\mathrm{B} \longrightarrow \text{Products}$$

the concentrations C_A and C_B inside the catalyst pellet are interrelated via the microscale mass balance, which yields for arbitrary catalyst geometries

$$\mathbb{D}_{\mathrm{i,B}}\left(C_{\mathrm{B,i}} - C_\mathrm{B}\right) = \nu \mathbb{D}_{\mathrm{i,A}}\left(C_{\mathrm{A,i}} - C_\mathrm{A}\right) \tag{6.118}$$

For convenience, the *excess number for bimolecular reactions* is introduced [37]:

$$\gamma = \nu \frac{\mathbb{D}_{\mathrm{i,A}}}{\mathbb{D}_{\mathrm{i,B}}} \frac{C_{\mathrm{A,i}}}{C_{\mathrm{B,i}}} \tag{6.119}$$

Component A is chosen as the key reactant, so that B is present in excess; thus

$$0 < \gamma < 1 \tag{6.120}$$

$\gamma = 0$ represents a large excess of component B; if $\gamma = 1$ the molar quantities of A and B just match each other.

Equation (6.118) can now be written as

$$\frac{C_\mathrm{B}}{C_{\mathrm{B,i}}} = 1 - \gamma\left(1 - \frac{C_\mathrm{A}}{C_{\mathrm{A,i}}}\right) \tag{6.121}$$

By using this equation, the reaction rate, generally a function of both C_A and C_B, can be written as a function of C_A only:

$$\begin{aligned} &|\mathbb{R}\left(C_\mathrm{A}, C_\mathrm{B}\right)|_\mathrm{p} \\ &= |\mathbb{R}\left\{C_\mathrm{A}, C_{\mathrm{B,i}}\left[1 - \gamma\left(1 - C_\mathrm{A}/C_{\mathrm{A,i}}\right)\right]\right\}|_\mathrm{p} \end{aligned} \tag{6.122}$$

Substituting this in the definition of the Thiele modulus (Eq. 6.109) gives the generalized Thiele modulus for bimolecular reactions:

$$\varphi = \frac{V_\mathrm{p}}{A_\mathrm{p}} |\mathbb{R}_\mathrm{A}\left(C_{\mathrm{A,i}}, C_{\mathrm{B,i}}\right)|_\mathrm{p} \cdot \left(2\mathbb{D}_{\mathrm{i,A}} \int_0^{C_{\mathrm{A,i}}} |\mathbb{R}_\mathrm{A} \left\{C_\mathrm{A}, C_{\mathrm{B,i}}\left[1 - \gamma\left(1 - C_\mathrm{A}/C_{\mathrm{A,i}}\right)\right]\right\}|_\mathrm{p}\, \partial C_\mathrm{A}\right)^{-\frac{1}{2}} \tag{6.123}$$

For example, for (1,1)-kinetics

$$|\mathbb{R}\left(C_\mathrm{A}, C_\mathrm{B}\right)|_\mathrm{p} = k_\mathrm{p} C_\mathrm{A} C_\mathrm{B} \tag{6.124}$$

Equation (6.123) yields

$$\varphi = \frac{V_\mathrm{p}}{A_\mathrm{p}} \sqrt{\frac{k_\mathrm{p} C_{\mathrm{B,i}}}{\left(1 - \frac{\gamma}{3}\right)\mathbb{D}_{\mathrm{i,A}}}} \tag{6.125}$$

For $C_{\mathrm{B,i}}/C_{\mathrm{A,i}} \to \infty$ and hence $\gamma \to 0$, this yields

$$\varphi = \frac{V_\mathrm{p}}{A_\mathrm{p}} \sqrt{\frac{k_\mathrm{p} C_{\mathrm{B,i}}}{\mathbb{D}_{\mathrm{i,A}}}} \tag{6.126}$$

which is the generalized Thiele modulus for first-order kinetics with a rate constant $k_\mathrm{p}\, C_{\mathrm{B,i}}$. The physical explanation is that in view of the large excess of B, consumption of B in the pellet is negligible ($C_\mathrm{B} = C_{\mathrm{B,i}}$), so the rate equation reduces to

$$|\mathbb{R}\left(C_\mathrm{A}, C_\mathrm{B}\right)|_\mathrm{p} = \left(k_\mathrm{p} C_{\mathrm{B,i}}\right) C_\mathrm{A} \tag{6.127}$$

Similarly, for $\gamma = 1$, according to Equation (6.121), apparent second-order kinetics are obtained:

$$|\mathbb{R}\left(C_\mathrm{A}, C_\mathrm{B}\right)|_\mathrm{p} = \left(k_\mathrm{p} \frac{C_{\mathrm{B,i}}}{C_{\mathrm{A,i}}}\right) C_\mathrm{A}^2 \tag{6.128}$$

hence, according to Equation (6.112),

$$\varphi = \frac{V_\mathrm{p}}{A_\mathrm{p}} \sqrt{\frac{3}{2} \frac{k_\mathrm{p} C_{\mathrm{B,i}}}{\mathbb{D}_{\mathrm{i,A}}}} \tag{6.129}$$

This is consistent with Equation (6.125), as can be seen by substituting $\gamma = 1$.

The definition of the generalized Thiele modulus (Eq. 6.123) is readily applicable to bimolecular reactions with more complex kinetics. For example, for Langmuir – Hinshelwood kinetics, (see Eq. 3.75):

$$|\mathbb{R}\left(C_\mathrm{A}, C_\mathrm{B}\right)|_\mathrm{p} = \frac{k_\mathrm{p} C_\mathrm{A} C_\mathrm{B}}{\left(1 + K_\mathrm{A} C_\mathrm{A} + K_\mathrm{B} C_\mathrm{B}\right)^2} \tag{6.130}$$

Equation (6.123) yields

$$\varphi = \frac{V_\mathrm{p}}{A_\mathrm{p}} \sqrt{\frac{1}{2} \frac{k_\mathrm{p} C_{\mathrm{B,i}}}{\mathbb{D}_{\mathrm{i,A}}}} \cdot \frac{K_\mathrm{A} C_{\mathrm{A,i}} + \gamma K_\mathrm{B} C_{\mathrm{B,i}}}{\left(1 + K_\mathrm{A} C_{\mathrm{A,i}} + K_\mathrm{B} C_{\mathrm{B,i}}\right)^2} \cdot \sqrt{\left[2\gamma\left(1 + \beta\right) - 1\right]\left(\frac{1}{1 + \beta} - \ln\frac{1 + \beta}{\beta}\right)} \tag{6.131}$$

with

$$\beta = \frac{1+(1-\gamma)\,K_{\mathrm{B}} C_{\mathrm{B,i}}}{K_{\mathrm{A}}\,C_{\mathrm{A,i}} + \gamma K_{\mathrm{B}}\,C_{\mathrm{B,i}}} \tag{6.132}$$

In a similar way, expressions for other types of kinetics can be found.

If the reaction rate depends on the concentrations of more than two components, the Thiele moduli can be calculated by using the same approach outlined above. For example, for the following equilibrium:

$$>\mathrm{A} + \nu_{\mathrm{B}}\,\mathrm{B} \rightleftharpoons \nu_{\mathrm{P}}\,\mathrm{P} + \nu_{\mathrm{Q}}\,\mathrm{Q}$$

where A is the key reactant (thus B is present in excess and the overall conversion is to the right), the rate equation is given by

$$|\mathbb{R}\left(C_{\mathrm{A}}, C_{\mathrm{B}}, C_{\mathrm{P}}, C_{\mathrm{Q}}\right)|_{\mathrm{p}} = k_{\mathrm{p}}\left(C_{\mathrm{A}} C_{\mathrm{B}} - \frac{C_{\mathrm{P}}\,C_{\mathrm{Q}}}{K}\right) \tag{6.133}$$

As in the derivation for bimolecular reactions,

$$\gamma_{\mathrm{B}} = \nu_{\mathrm{B}} \frac{\mathbb{D}_{\mathrm{i,A}}}{\mathbb{D}_{\mathrm{i,B}}} \frac{C_{\mathrm{A,i}}}{C_{\mathrm{B,i}}} \tag{6.134}$$

$$\gamma_{\mathrm{P}} = \nu_{\mathrm{P}} \frac{\mathbb{D}_{\mathrm{i,A}}}{\mathbb{D}_{\mathrm{i,P}}} \frac{C_{\mathrm{A,i}}}{C_{\mathrm{P,i}}} \tag{6.135}$$

$$\gamma_{\mathrm{Q}} = \nu_{\mathrm{Q}} \frac{\mathbb{D}_{\mathrm{i,A}}}{\mathbb{D}_{\mathrm{i,Q}}} \frac{C_{\mathrm{A,i}}}{C_{\mathrm{Q,i}}} \tag{6.136}$$

Microscale mass balances now yield

$$\frac{C_{\mathrm{B}}}{C_{\mathrm{B,i}}} = 1 - \gamma_{\mathrm{B}}\left(1 - \frac{C_{\mathrm{A}}}{C_{\mathrm{A,i}}}\right) \tag{6.137}$$

$$\frac{C_{\mathrm{P}}}{C_{\mathrm{P,i}}} = 1 + \gamma_{\mathrm{P}}\left(1 - \frac{C_{\mathrm{A}}}{C_{\mathrm{A,i}}}\right) \tag{6.138}$$

$$\frac{C_{\mathrm{Q}}}{C_{\mathrm{Q,i}}} = 1 + \gamma_{\mathrm{Q}}\left(1 - \frac{C_{\mathrm{A}}}{C_{\mathrm{A,i}}}\right) \tag{6.139}$$

Hence the reaction rate can be expressed in concentration C_{A} only (cf. Eq. 6.133):

$$\begin{aligned} &|\mathbb{R}\left(C_{\mathrm{A}}, C_{\mathrm{B}}, C_{\mathrm{P}}, C_{\mathrm{Q}}\right)|_{\mathrm{p}} \\ &= k_{\mathrm{p}}\left\{C_{\mathrm{A}} C_{\mathrm{B,i}}\left[1 - \gamma_{\mathrm{B}}\left(1 - C_{\mathrm{A}}/C_{\mathrm{A,i}}\right)\right]\right. \\ &- \frac{C_{\mathrm{P,i}} C_{\mathrm{Q,i}}}{K}\left[1 + \gamma_{\mathrm{P}}\left(1 - C_{\mathrm{A}}/C_{\mathrm{A,i}}\right)\right] \\ &\left.\cdot\left[1 + \gamma_{\mathrm{Q}}\left(1 - C_{\mathrm{A}}/C_{\mathrm{A,i}}\right)\right]\right\} \end{aligned} \tag{6.140}$$

Substitution in the definition of the Thiele modulus gives

$$\varphi = \frac{V_{\mathrm{p}}}{A_{\mathrm{p}}}\,|\mathbb{R}_{\mathrm{A}}\left(C_{\mathrm{A,i}}, C_{\mathrm{B,i}}, C_{\mathrm{P,i}}, C_{\mathrm{Q,i}}\right)|_{\mathrm{p}} \cdot \left(2\,\mathbb{D}_{\mathrm{i,A}} \int_0^{C_{\mathrm{A,i}}} |\mathbb{R}_{\mathrm{A}}\left(C_{\mathrm{A}}, C_{\mathrm{B}}, C_{\mathrm{P}}, C_{\mathrm{Q}}\right)|_{\mathrm{p}}\,\partial C_{\mathrm{A}}\right)^{-\frac{1}{2}} \tag{6.141}$$

which yields the generalized Thiele modulus for equilibrium reactions:

$$\varphi = \frac{V_{\mathrm{p}}}{A_{\mathrm{p}}}\left(1 - \frac{C_{\mathrm{P,i}} C_{\mathrm{Q,i}}}{K C_{\mathrm{A,i}} C_{\mathrm{B,i}}}\right) \cdot \sqrt{\frac{k_{\mathrm{p}} C_{\mathrm{B,i}}}{\mathbb{D}_{\mathrm{i,A}}\left[1 - \frac{\gamma_{\mathrm{B}}}{3} - \frac{C_{\mathrm{P,i}} C_{\mathrm{Q,i}}}{K C_{\mathrm{A,i}} C_{\mathrm{B,i}}}\left(2 + \gamma_{\mathrm{P}} + \gamma_{\mathrm{Q}} - \frac{\gamma_{\mathrm{P}}\gamma_{\mathrm{Q}}}{3}\right)\right]}} \tag{6.142}$$

For bimolecular reactions, the mathematics necessary to derive the exact equations for η are generally impossible to solve and numerical techniques must be used. Thus to estimate η, approximation equations (Eqs. 6.116 and 6.117) are generally used. Again, the error introduced when using one of the above approximations can be quite substantial, especially for low (apparent) reaction orders. Equations (6.116) and (6.117) are exact only in the low η regime, where $\eta = 1\varphi$.

6.2.2.5. Anisotropic Catalyst Pellets

Cylindrical catalyst pellets, with or without a hole in the center, are usually shaped by extrusion of a "wet" catalyst paste. During this process the diameter of the pores in the radial direction may become smaller, and the length of pores in the longitudinal direction may decrease. This can result in the radial effective diffusivity being lower than the longitudinal one. Thus cylindrical catalyst pellets can be anisotropic. This anisotropy can be accounted for in the Thiele modulus. Consider, for example, a ring-shaped catalyst pellet; here, for monomolecular reactions a microscale mass balance yields (see Eq. 6.97)

$$\mathbb{D}^{r}_{\mathrm{i,A}} \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial C_{\mathrm{A}}}{\partial r}\right) + \mathbb{D}^{h}_{\mathrm{i,A}} \frac{\partial^2 C_{\mathrm{A}}}{\partial h^2} = |\mathbb{R}_{\mathrm{A}}|_{\mathrm{p}} \tag{6.143}$$

If

$$r^* = r\sqrt{\frac{\mathbb{D}^{h}_{\mathrm{i,A}}}{\mathbb{D}^{r}_{\mathrm{i,A}}}} \tag{6.144}$$

is substituted, Equation (6.143) can be written as

$$\mathbb{D}^h_{\mathrm{i,A}}\left[\frac{1}{r^*}\frac{\partial}{\partial r^*}\left(r^*\frac{\partial C_\mathrm{A}}{\partial r^*}\right)+\frac{\partial^2 C_\mathrm{A}}{\partial h^2}\right]=|\mathbb{R}_\mathrm{A}|_\mathrm{p} \quad (6.145)$$

The differential Equation (6.145) describes the concentration profile in an isotropic ring-shaped catalyst pellet with an effective diffusion coefficient $\mathbb{D}^h_{\mathrm{i,A}}$, an inner radius

$$R^*_\mathrm{i}=R_\mathrm{i}\sqrt{\frac{\mathbb{D}^h_{\mathrm{i,A}}}{\mathbb{D}^r_{\mathrm{i,A}}}} \quad (6.146)$$

and an outer radius

$$R^*_\mathrm{u}=R_\mathrm{u}\sqrt{\frac{\mathbb{D}^h_{\mathrm{i,A}}}{\mathbb{D}^r_{\mathrm{i,A}}}} \quad (6.147)$$

Hence, anisotropy can be accounted for in the Thiele modulus if the effective diffusion coefficient $\mathbb{D}_{\mathrm{i,A}}$ is replaced by $\mathbb{D}^h_{\mathrm{i,A}}$ and the characteristic dimension $V_\mathrm{p}/A_\mathrm{p}$ by

$$\left(\frac{V_\mathrm{p}}{A_\mathrm{p}}\right)^*=\frac{1}{2}\left(\frac{1}{H}+\frac{1}{R^*_\mathrm{u}-R^*_\mathrm{i}}\right)$$
$$=\frac{1}{2}\left(\frac{1}{H}\frac{1}{R_\mathrm{u}-R_\mathrm{i}}\sqrt{\frac{\mathbb{D}^r_{\mathrm{i,A}}}{\mathbb{D}^h_{\mathrm{i,A}}}}\right) \quad (6.148)$$

Thus, the following equation is obtained for the generalized Thiele modulus for monomolecular reactions (cf. Eq. 6.109):

$$\varphi=\left(\frac{V_\mathrm{p}}{A_\mathrm{p}}\right)^*|\mathbb{R}_\mathrm{A}\left(C_\mathrm{A,i}\right)|_\mathrm{p}\cdot\left(2\mathbb{D}^h_{\mathrm{i,A}}\int_0^{C_\mathrm{A,i}}|\mathbb{R}_\mathrm{A}\left(C_\mathrm{A}\right)|_\mathrm{p}\,\partial C_\mathrm{A}\right)^{-\frac{1}{2}} \quad (6.149)$$

Rather than accounting for anisotropy by modifying both the characteristic dimension and the effective diffusion coefficient, anisotropy is accounted for by modifying the effective diffusion coefficient only. Thus, for anisotropic catalyst pellets a modified effective diffusion coefficient $\mathbb{D}^*_{\mathrm{i,A}}$ is defined. Consequently, for anisotropic catalyst pellets and monomolecular reactions the generalized Thiele modulus follows from

$$\varphi=\frac{V_\mathrm{p}}{A_\mathrm{p}}|\mathbb{R}_\mathrm{A}\left(C_\mathrm{A,i}\right)|_\mathrm{p}\cdot\left(2\mathbb{D}^*_{\mathrm{i,A}}\int_0^{C_\mathrm{A,i}}|\mathbb{R}_\mathrm{A}\left(C_\mathrm{A}\right)|_\mathrm{p}\,\partial C_\mathrm{A}\right)^{-\frac{1}{2}} \quad (6.150)$$

Comparison of Equations (6.148)–(6.150) shows that for ring-shaped catalyst pellets the modified effective diffusion coefficient $\mathbb{D}^*_{\mathrm{i,A}}$ follows from

$$\mathbb{D}^*_{\mathrm{i,A}}=\left(\frac{\frac{\sqrt{\mathbb{D}^r_{\mathrm{i,A}}}}{R_\mathrm{u}-R_\mathrm{i}}+\frac{\sqrt{\mathbb{D}^h_{\mathrm{i,A}}}}{H}}{\frac{1}{R_\mathrm{u}-R_\mathrm{i}}+\frac{1}{H}}\right)^2 \quad (6.151)$$

Therefore, all conclusions drawn for isotropic catalyst pellets also hold for anisotropic catalyst pellets. For example for bimolecular reactions,

$$\varphi=\frac{V_\mathrm{p}}{A_\mathrm{p}}|\mathbb{R}_\mathrm{A}\left(C_\mathrm{A,i},C_\mathrm{B,i}\right)|_\mathrm{p}\cdot\left(2\mathbb{D}^*_{\mathrm{i,A}}\int_0^{C_\mathrm{A,i}}|\mathbb{R}_\mathrm{A}\left\{C_\mathrm{A},C_\mathrm{B,i}\right.\right.$$
$$\left.\left.\left[1-\gamma\left(1-C_\mathrm{A}/C_\mathrm{A,i}\right)\right]\right\}|_\mathrm{p}\,\partial C_\mathrm{A}\right)^{-\frac{1}{2}} \quad (6.152)$$

to be compared with Equation (6.123). As a matter of fact, with a single, constant catalyst geometry, no distinction is possible between isotropic and anisotropic pellets. The effect of anisotropy is lumped in the effective diffusion coefficient. If the catalyst pellet is *isotropic*, from Equation (6.151) the effective diffusion coefficient $\mathbb{D}_{\mathrm{i,A}}=\mathbb{D}^*_{\mathrm{i,A}}=\mathbb{D}^r_{\mathrm{i,A}}=\mathbb{D}^h_{\mathrm{i,A}}$ is measured. For *anisotropic pellets*, $\mathbb{D}^r_{\mathrm{i,A}}$ for pellets with a large height and $\mathbb{D}^h_{\mathrm{i,A}}$ for flat pellets are measured. For intermediate geometries the value of $\mathbb{D}^*_{\mathrm{i,A}}$ is between $\mathbb{D}^r_{\mathrm{i,A}}$ and $\mathbb{D}^h_{\mathrm{i,A}}$. The only situation in which anisotropy can give rise to errors is when the catalyst geometry–thus $(R_u-R_\mathrm{i})/H$–is changed, and the value of the effective diffusion coefficient is used, which was determined for another catalyst geometry. The procedure discussed above can readily be extended to other catalyst geometries. Consider the purely academic example of an anisotropic parallelepiped with the dimesions of width×length×height = $W\times L\times H$. Here the Thiele modulus can still be calculated from Equations (6.150) and (6.152). However, the modifed effective diffusion coefficient now becomes

$$\mathbb{D}^*_{\mathrm{i,A}}=\left(\frac{\frac{\sqrt{\mathbb{D}^w_{\mathrm{i,A}}}}{W}+\frac{\sqrt{\mathbb{D}^l_{\mathrm{i,A}}}}{L}+\frac{\sqrt{\mathbb{D}^h_{\mathrm{i,A}}}}{H}}{\frac{1}{W}+\frac{1}{L}+\frac{1}{H}}\right)^2 \quad (6.153)$$

6.2.3. Reactions of Gases in Liquids – Part I: Gaseous Reactants Only

6.2.3.1. Introduction

In this section, simultaneous reaction and mass transfer in a liquid phase are discussed, where the reactant or all of the reactants are absorbed from a gas phase in contact with this liquid. The assumption is that mass transfer on the gas-phase side of the gas – liquid interface is infinitely fast, so that it need not be considered.

For gas – liquid reactions in general, two cases can be distinguished:

1) A reactant or reactants are absorbed from the gas to react in the liquid. No components already present in the liquid are consumed in the reaction.
2) A reactant is absorbed from the gas to react in the liquid with an already dissolved component.

The former situation is discussed in Section 6.2.3, the latter in Section 6.2.4.

Although in the following a reactant is being absorbed from a gas phase, the theory can, of course, be used for a situation in which two immiscible liquids exist and a reactant is transported from one of the liquids to react in the other.

According to the models already presented, on the liquid side of the gas – liquid interface there is either an interface covered with small stagnant fluid elements or a stagnant film with a negligible curvature at the interface. Therefore the penetration and film models are the basis of the calculations for these cases.

6.2.3.2. Higbie Penetration Model

A small stagnant liquid element is attached to the interface for a contact time τ. In the period from 0 to τ the reactant is transferred into the liquid; simultaneously it reacts in that liquid. After τ s the element detaches to mix with the bulk of the liquid. The transient concentration profile in the element can be derived from Equation (5.10) with the extension of a reaction term:

$$\frac{\partial C_{\mathrm{A}}}{\partial t} = \mathbb{D}_{\mathrm{i,A}} \frac{\partial^2 C_{\mathrm{A}}}{\partial x^2} - |\mathbb{R}_{\mathrm{A}}| \tag{6.154}$$

to be solved subject to the boundary conditions

$$x = 0 \Rightarrow C_{\mathrm{A}} = C_{\mathrm{A,i}} \tag{6.155}$$

$$x \to \infty \Rightarrow C_{\mathrm{A}} = \overline{C_{\mathrm{A}}} \tag{6.156}$$

where $\overline{C_{\mathrm{A}}}$ is the concentration of A in the bulk of the liquid. The initial condition for Equation (6.154) is

$$t = 0 \Rightarrow C_{\mathrm{A}} = 0 \tag{6.157}$$

If A disappears by a first-order reaction, the above equation becomes

$$\frac{\partial C_{\mathrm{A}}}{\partial t} = \mathbb{D}_{\mathrm{A}} \frac{\partial^2 C_{\mathrm{A}}}{\partial x^2} - k C_{\mathrm{A}} \tag{6.158}$$

If the bulk concentration $\overline{C_{\mathrm{A}}} = 0$, Equation (6.158) gives [38]

$$\begin{aligned} \frac{C_{\mathrm{A}}}{C_{\mathrm{A,i}}} &= \frac{1}{2} \exp\left(-x\sqrt{\frac{k}{\mathbb{D}_{\mathrm{A}}}}\right) \\ &\quad \cdot \left[1 - \operatorname{erf}\left(\frac{x}{2\sqrt{\mathbb{D}_{\mathrm{A}} t}} - \sqrt{k t}\right)\right] \\ &+ \frac{1}{2} \exp\left(+x\sqrt{\frac{k}{\mathbb{D}_{\mathrm{A}}}}\right) \\ &\quad \cdot \left[1 - \operatorname{erf}\left(\frac{x}{2\sqrt{\mathbb{D}_{\mathrm{A}} t}} - \sqrt{k t}\right)\right] \end{aligned} \tag{6.159}$$

Differentiation and substitution of $x = 0$ give the flux through the interface:

$$\begin{aligned} J_{\mathrm{A}} &= -\mathbb{D}_{\mathrm{A}} \left(\frac{\partial C_{\mathrm{A}}}{\partial x}\right)\Big|_{x=0} \\ &= \sqrt{k \mathbb{D}_{\mathrm{A}}} \left[\operatorname{erf}\left(\sqrt{k t}\right) + \frac{\exp(-k t)}{\sqrt{\pi k t}}\right] C_{\mathrm{A,i}} \end{aligned} \tag{6.160}$$

The average mass-transfer rate between 0 and τ s follows from

$$\begin{aligned} \overline{J_{\mathrm{A}}} &= \frac{1}{\tau} \int_0^{\tau} J_{\mathrm{A}}\, \partial t = \sqrt{k \mathbb{D}_{\mathrm{A}}} \left[\left(1 + \frac{1}{2k\tau}\right) \operatorname{erf}\left(\sqrt{k\tau}\right)\right. \\ &\quad \left. + \frac{\exp(-k\tau)}{\sqrt{\pi k \tau}}\right] C_{\mathrm{A,i}} \end{aligned} \tag{6.161}$$

Equation (6.161) gives the mass-transfer rate according to the Higbie model for $\overline{C_{\mathrm{A}}} = 0$. In Figure 33, J_{A} and $\overline{J_{\mathrm{A}}}$ are plotted versus t and τ, respectively. Both fluxes decrease with increasing t as well as increasing τ.

Figure 33. Molar flux $J_A(t)$ as a function of time (t) and average molar flux $\overline{J_A}(\tau)$ as a function of contact time (τ) for mass transfer with simultaneous first-order reaction, according to the Higbie penetration model

By using Equation (5.26), the Higbie contact time τ can be expressed in terms of k_l, the mass-transfer coefficient of A in the liquid phase as

$$\tau = \frac{4\mathbb{D}_A}{\pi k_l^2} \tag{6.162}$$

Substitution of this expression for τ in Equation (6.161) gives

$$\overline{J_A} = k_l C_{A,i} \frac{\sqrt{k\mathbb{D}_A}}{k_l} \left[\left(1 + \frac{\pi k_l^2}{8k\mathbb{D}_A}\right) \cdot \mathrm{erf}\left(\frac{2}{\sqrt{\pi}} \frac{\sqrt{k\mathbb{D}_A}}{k_l}\right) + \frac{1}{2} \frac{k_l}{\sqrt{k\mathbb{D}_A}} \cdot \exp\left(-\frac{4}{\pi} \frac{k\mathbb{D}_A}{k_l^2}\right)\right] \tag{6.163}$$

The dimensionless group $\sqrt{k\mathbb{D}_A/k_l}$ is known as the *Hatta number Ha*:

$$Ha = \frac{\sqrt{k\mathbb{D}_A}}{k_l} \tag{6.164}$$

The Hatta number is a measure of the ratio of the reaction rate to the rate of mass transfer of component A. Substituting Equation (6.164) in Equation (6.163) yields

$$\overline{J_A} = k_l C_{A,i} Ha \left[\left(1 + \frac{\pi}{8Ha^2}\right) \mathrm{erf}\left(\frac{2Ha}{\sqrt{\pi}}\right) + \frac{1}{2Ha} \exp\left(-\frac{4Ha^2}{\pi}\right)\right] \tag{6.165}$$

Asymptotic solutions for $\overline{J_A}$ are obtained for

1) $Ha < 0.2$

$$\overline{J_A} = k_l C_{A,i} \tag{6.166}$$

i.e., Ha is so small, or the reaction is so slow compared to mass transfer, that Equation (6.165) reduces to the equation for mass transfer without reaction

2) $Ha < 0.5$

$$\overline{J_A} = k_l C_{A,i} \left(1 + \frac{4Ha^2}{3\pi}\right) \tag{6.167}$$

3) $Ha > 1$

$$\overline{J_A} = k_l C_{A,i} Ha \left(1 + \frac{\pi}{8Ha^2}\right) \tag{6.168}$$

4) $Ha > 2$

$$\overline{J_A} = k_l C_{A,i} Ha \tag{6.169}$$

In the last three cases (i.e., roughly for $Ha > 0.2$), the transfer rate is enhanced compared to the rate obtained in the absence of reaction due to the reaction that occurs. This is a result of the increase of $\partial C_A/\partial x$ at the interface, because of a decrease in the concentration of A by reaction. A frequently used term is the so-called *enhancement factor* E_A defined as

$$E_A = \frac{\overline{J_A} \text{ with reaction}}{\overline{J_A} \text{ without reaction}} \tag{6.170}$$

where both fluxes $\overline{J_A}$ are based on the same $C_{A,i}$. Thus it follows from the above analysis that the enhancement factor E_A varies, according to the Higbie penetration model, from $E_A = 1$ (for $Ha < 0.2$) to $E_A = Ha$ (for $Ha > 2$), provided the reaction is first-order and provided the bulk concentration of A in the liquid is zero. In general, for this situation the Higbie penetration model yields

$$E_A = Ha \left[\left(1 + \frac{\pi}{8Ha^2}\right) \mathrm{erf}\left(\frac{2Ha}{\sqrt{\pi}}\right) + \frac{1}{2Ha} \exp\left(-\frac{4Ha^2}{\pi}\right)\right] \tag{6.171}$$

6.2.3.3. Surface Renewal Model

Starting from his modification of the penetration theory (i.e., again small stagnant liquid elements are attached to the interface, all elements have the same chance to be replaced by other elements and mix with the bulk of the liquid), DANCKWERTS derived the following expression for mass transfer with a first-order reaction in a liquid [6]

$$\overline{J_A} = k_l \left(C_{A,i} - \frac{\overline{C_A}}{1+Ha^2} \right) \sqrt{1+Ha^2} \tag{6.172}$$

This solution is relatively simple compared to the Higbie solution (Eq. 6.165), which is all the more remarkable because the Danckwerts solution also covers the case in which the concentration of A in the liquid bulk differs from zero. In the case of mass transfer of A to the liquid phase, $\overline{C_A} \leq C_{A,i}$ must hold, so that, roughly, for $Ha > 2$ the term $\overline{C_A}/(1+Ha^2)$ can be neglected in Equation (6.172).

The enhancement factor E_A defined as (see Eq. 6.170)

$$E_A = \frac{\overline{J_A}}{k_l \left(C_{A,i} - \overline{C_A} \right)} \tag{6.173}$$

follows from Equation (6.172)

$$E_A = \sqrt{1+Ha^2} \cdot \left(1 + \frac{\overline{C_A}}{C_{A,i} - \overline{C_A}} \frac{Ha^2}{1+Ha^2} \right) \tag{6.174}$$

For slow reactions ($Ha < 0.2$) the same asymptotic solution is found as with the Higbie model ($E_A = 1$). For fast reactions ($Ha > 2$), generally $\overline{C_A} \approx 0$; hence, the same asymptotic solution is also found as with the Higbie model ($E_A = Ha$). For the regime $0.2 < Ha < 2$ and $\overline{C_A} \neq 0$, E_A depends on the concentrations $C_{A,i}$ and $\overline{C_A}$. In this case, $\overline{J_A}$ is not proportional to the driving force $(C_{A,i} - \overline{C_A})$, as is the case for absorption without reaction. In practice, however, this situation does not occur frequently.

6.2.3.4. Stagnant Film Model

In the stagnant film model the following assumptions are made (see Section 5.3): the fluid is divided in a stagnant film near the interface with a thickness δ and a well-mixed bulk behind it; mass transfer is a stationary process; and the radius of curvature of the interface is large compared to the film thickness. Thus, in the case of homogeneous reaction, Equation (5.20) must be extended by a chemical reaction term

$$\frac{\partial^2 C_A}{\partial x^2} = |\mathbb{R}_A| \quad \text{for } 0 < x < \delta \tag{6.175}$$

The boundary conditions are the same as without reaction:

$$x = 0 \Rightarrow C_A = C_{A,i} \tag{5.21}$$

$$x = \delta \Rightarrow C_A = \overline{C_A} \tag{5.22}$$

The solution of Equations (6.175), (5.21), and (5.22) for first-order kinetics, i.e., $-\mathbb{R}_A- = k\,C_A$, gives, for $0 \leq x \leq \delta$:

$$\frac{C_A}{C_{A,i}} = \frac{\sinh\left[(\delta - x)\sqrt{\frac{k}{\mathbb{D}_A}}\right] + \frac{\overline{C_A}}{C_{A,i}} \sinh\left(x\sqrt{\frac{k}{\mathbb{D}_A}}\right)}{\sinh\left(\delta\sqrt{\frac{k}{\mathbb{D}_A}}\right)} \tag{6.176}$$

Differentiation and substitution of $x = 0$ give the flux through the interface:

$$\overline{J_A} = -\mathbb{D}_A \left(\frac{\partial C_A}{\partial x} \right)\Big|_{x=0} = \frac{\mathbb{D}_A}{\delta} C_{A,i} \cdot \delta \sqrt{\frac{k}{\mathbb{D}_A}} \frac{1}{\tanh\left(\delta\sqrt{\frac{k}{\mathbb{D}_A}}\right)} - \frac{\frac{\overline{C_A}}{C_{A,i}}}{\sinh\left(\delta\sqrt{\frac{k}{\mathbb{D}_A}}\right)} \tag{6.177}$$

From Equation (5.27) the mass-transfer coefficient according to the stagnant film model is found as

$$k_l = \frac{\mathbb{D}_A}{\delta} \tag{6.178}$$

The Hatta number thus becomes

$$Ha = \frac{\sqrt{k\mathbb{D}_A}}{k_l} = \delta\sqrt{\frac{k}{\mathbb{D}_A}} \tag{6.179}$$

Substitution of Equations (6.178) and (6.179) in Equation (6.177) gives

$$\overline{J_A} = k_l C_{A,i} \frac{Ha}{\tanh(Ha)} \left[1 - \frac{\overline{C_A}}{C_{A,i}} \frac{1}{\cosh(Ha)} \right] \tag{6.180}$$

Hence the enhancement factor E_A according to the stagnant film model becomes

$$E_A = \frac{Ha}{\tanh(Ha)} \left\{ 1 + \frac{\overline{C_A}}{C_{A,i} - \overline{C_A}} \left[1 - \frac{1}{\cosh(Ha)} \right] \right\} \tag{6.181}$$

Again, the same asymptotic solutions are found as with the penetration models ($E_A = 1$ and $E_A = Ha$ for $Ha < 0.2$ and $Ha > 2$, respectively). For the regime $0.2 < Ha < 2$ and $\overline{C_A} \neq 0$, E_A again depends on the concentration, in which case $\overline{J_A}$ is not proportional to the driving force $(C_{A,i} - \overline{C_A})$, as is the case for absorption without reaction. As already discussed, in practice this situation is seldom met.

6.2.3.5. Comparison of Models for First-Order Kinetics

In Sections 6.2.3.2, 6.2.3.3, and 6.2.3.4, analytical expressions have been presented for simultaneous mass transfer and irreversible first-order reactions according to the penetration models of Higbie and Danckwerts and the film model. Numerically, the differences between the three models are not very pronounced. All three models predict the same asymptotic solutions for $Ha < 0.2$ and $Ha > 2$, respectively. The differences are maximal for Hatta numbers roughly equal to unity. Even in this case the enhancement factors calculated from the three models agree within 10 % for $\overline{C_A} = 0$ and within 20 % for $\overline{C_A} \neq 0$. For example, for $Ha = 1$ and $\overline{C_A} = 0$ from Equations (6.171), (6.174), and (6.181),

Stagnant film	$E_A = 1.31$
Higbie penetration	$E_A = 1.38$
Danckwerts penetration	$E_A = 1.41$

For $Ha = 1$ and $\overline{C_A} = C_{A,i}/2$,

Stagnant film	$E_A = 1.78$
Danckwerts penetration	$E_A = 2.12$

However, as mentioned, for fast reactions the bulk concentration $\overline{C_A}$ can be assumed to be zero for almost all practical cases, so that the situation $Ha = 1$ and $\overline{C_A} = C_{A,i}/2$ is not often encountered.

The agreement between the enhancement factors is very satisfactory for most engineering purposes. Therefore, the distinction between the different models is generally not relevant. The Hatta number is usually calculated from the (measured) mass-transfer coefficient k_l (Eq. 6.164):

$$Ha = \frac{\sqrt{k\mathbb{D}_A}}{k_l}$$

Then the enhancement factor is estimated from one of the following equations:

$$E_A = \sqrt{1 + Ha^2} \tag{6.182}$$

or

$$E_A = \frac{Ha}{\tanh(Ha)} \tag{6.183}$$

These equations are generally selected because they are easy to use.

In the *fast reaction regime* ($Ha > 2$), all models predict

$$\overline{J_A} = k_l C_{A,i} Ha = \sqrt{k\mathbb{D}_A} C_{A,i} \tag{6.184}$$

Thus, for $Ha > 2$, the rate of mass transfer becomes independent of the mass-transfer coefficient. This result is far reaching; it implies that the overall conversion rate does not depend on local hydrodynamics near the gas – liquid interface. Furthermore, the bulk concentration $\overline{C_A}$ becomes zero, which implies that information on the exact flow pattern in the bulk of the liquid phase (e.g., macromixing) is not required for design purposes. Both facts may substantially simplify (experiments necessary for) the design of the reactor.

In the *slow reaction regime* ($Ha < 0.2$), all models predict

$$\overline{J_A} = k_l \left(C_{A,i} - \overline{C_A} \right) \tag{6.185}$$

Thus, the reaction does not enhance the rate of mass transfer in this case.

6.2.3.6. Comparison of Hatta Numbers with Thiele Moduli

In this section the film model is used for discussions of gas – liquid reactions because of its simplicity and mediative power. With the penetration models, however, the same conclusions would have been obtained.

The Hatta numbers and the Thiele moduli discussed in the previous section are very similar because, for both high Hatta numbers and

high Thiele moduli the penetration depth of A in the stagnant film or in the porous pellet is so small, that the thickness of the film with respect to the geometry of the pellet becomes irrelevant. For Hatta numbers this can be derived from Equation (6.184), where it is shown that for high Hatta numbers and first-order kinetics, the overall mole flux is not a function of k_1 (i.e., film thickness δ):

$$\overline{J_{\mathrm{A}}} = \sqrt{k\mathbb{D}_{\mathrm{A}}}\, C_{\mathrm{A,i}} \tag{6.186}$$

For porous pellets with high Thiele moduli and first-order kinetics, the effectiveness factor η becomes

$$\eta = \frac{1}{\varphi} = \frac{A_{\mathrm{p}}}{V_{\mathrm{p}}}\sqrt{\frac{\mathbb{D}_{\mathrm{i,A}}}{k}} \tag{6.187}$$

The number of moles of A converted within the porous pellet equals $V_{\mathrm{p}} — \mathbb{R}_{\mathrm{A}} —_{\mathrm{p}} \eta$; hence the overall flux through the pellet outer surface is

$$\overline{J_{\mathrm{A}}} = \frac{V_{\mathrm{p}}\,|\mathbb{R}_{\mathrm{A}}|_{\mathrm{p}}}{A_{\mathrm{p}}}\eta$$
$$= \frac{V_{\mathrm{p}}}{A_{\mathrm{p}}}\, k_{\mathrm{p}} C_{\mathrm{A,i}}\, \frac{A_{\mathrm{p}}}{V_{\mathrm{p}}}\sqrt{\frac{\mathbb{D}_{\mathrm{i,A}}}{k}} = \sqrt{k_{\mathrm{p}}\mathbb{D}_{\mathrm{i,A}}}\, C_{\mathrm{A,i}} \tag{6.188}$$

which is similar to Equation (6.186).

In general, the Thiele modulus and Hatta number are identical: they differ only in the characteristic dismension. For the Thiele modulus this is the generalized pellet dimension $V_{\mathrm{p}}/A_{\mathrm{p}}$ introduced by ARIS, whereas for the Hatta number it is the characteristic dimension of the film $(V/A)_{\mathrm{film}}$ (i.e., the thickness δ, or alternatively written $\mathbb{D}_{\mathrm{A}}/k_1$). Thus,

$$Ha = \left(\frac{\mathbb{D}_{\mathrm{A}}}{k_1}\frac{A_{\mathrm{p}}}{V_{\mathrm{p}}}\right)\varphi \tag{6.189}$$

Sometimes a distinction between Hatta numbers and Thiele moduli is made, and sometimes reference is made to a single parameter (e.g., φ) that covers both numbers (e.g., see [8]).

For reactions with mass transfer in porous solids, the terms *effectiveness factor* and *retardation of reaction by mass transfer* are used, whereas for reactions with mass transfer of gases in liquids, *enhancement factor* and *enhancement of mass transfer by reaction* are generally employed. This classification is logical because for reactions of gases in porous solids, it is difficult to visualize mass transfer without chemical reaction: since there is no such thing as bulk behind a film, for porous pellets, mass transfer simply becomes nonexistent in the absence of chemical reaction. Consequently, an enhancement factor definition (Eq. 6.170) is not applicable, and the use of an effectiveness factor is more logical. In contrast, for gas – liquid reactions there is a large liquid bulk behind the film. Therefore the idea of mass transfer without reaction makes sense and so does the definition of enhancement factor.

6.2.3.7. Hatta Numbers for Arbitrary Kinetics

From the similarity between Hatta numbers and Thiele moduli, it is clear that generalization of Hatta numbers for arbitrary kinetics proceeds along the same as lines discussed in Section 6.2.2 for Thiele moduli. Thus, for monomolecular reactions and arbitrary kinetics,

$$Ha = \frac{\mathbb{D}_{\mathrm{A}}}{k_1}\,|\mathbb{R}_{\mathrm{A}}\left(C_{\mathrm{A,i}}\right)| \cdot \left(2\mathbb{D}_{\mathrm{A}}\int_0^{C_{\mathrm{A,i}}} |\mathbb{R}_{\mathrm{A}}\left(C_{\mathrm{A}}\right)|\,\partial C_{\mathrm{A}}\right)^{-\frac{1}{2}} \tag{6.190}$$

For simple *n* th-*order kinetics*,

$$|\mathbb{R}_{\mathrm{A}}| = k\,C_{\mathrm{A}}^{n} \tag{6.191}$$

Equation (6.190) yields

$$Ha = \frac{\mathbb{D}_{\mathrm{A}}}{k_1}\sqrt{\frac{n+1}{2}\,\frac{k\,C_{\mathrm{A,i}}^{n-1}}{\mathbb{D}_{\mathrm{A}}}} \tag{6.192}$$

For *bimolecular reactions*,

$$\mathrm{A} + \nu B \longrightarrow \text{Products}$$

where both A and B are transferred from the gas to react in the liquid; $— \mathbb{R}\left(C_{\mathrm{A}}, C_{\mathrm{B}}\right) —$ can again be written as a function only of C_{A}

$$|\mathbb{R}\left(C_{\mathrm{A}}, C_{\mathrm{B}}\right)| = |\mathbb{R}\left\{C_{\mathrm{A}}, C_{\mathrm{B,i}}\left[1-\gamma\left(1-C_{\mathrm{A}}/C_{\mathrm{A,i}}\right)\right]\right\}| \tag{6.193}$$

where γ is again the excess factor, defined as

$$\gamma = \nu\frac{\mathbb{D}_{\mathrm{A}}}{\mathbb{D}_{\mathrm{B}}}\frac{C_{\mathrm{A,i}}}{C_{\mathrm{B,i}}} \tag{6.194}$$

Thus the generalized Hatta number for bimolecular reactions is obtained:

$$Ha = \frac{\mathbb{D}_A}{k_l} \left| \mathbb{R}_A \left(C_{A,i}, C_{B,i} \right) \right| \cdot \left(2\,\mathbb{D}_A \int_0^{C_{A,i}} \left| \mathbb{R}_A \left\{ C_A, C_{B,i} \cdot \left[1 - \gamma \left(1 - C_A / C_{A,i} \right) \right] \right\} \right| \partial C_A \right)^{-\frac{1}{2}} \tag{6.195}$$

which, for example, for (1,1) kinetics

$$\left| \mathbb{R} \left(C_A, C_B \right) \right|_p = k_p C_A C_B \tag{6.196}$$

yields

$$Ha = \frac{\mathbb{D}_A}{k_l} \sqrt{\frac{k C_{B,i}}{\left(1 - \frac{\gamma}{3}\right) \mathbb{D}_A}} \tag{6.197}$$

Equations (6.195) and (6.197) can be used only if both A and B are transferred from the gas and not if one of the components (e.g., B) is already dissolved in the liquid. All the above formulas can be compared readily with similar equations for the Thiele modulus discussed in Section 6.2.2.

6.2.3.8. Case Study: Ideally Mixed Gas – Liquid Reactors

As a case study, the discussed theory is applied to ideally mixed gas liquid reactors [i.e., reactors for which the bulk concentration in the liquid (reaction) phase and the interface concentration are constant over the entire reactor]. Thus, a short excursion is made from macrokinetics to the reactor level.

The case study is restricted to first-order kinetics and only the film model is used (see Fig. 34). Two important parameters for the type of reactor shown in Figure 34 are the *gas – liquid dispersion volume* V (m^3) and the *gas – liquid specific contact area* a (square meters of interface per cubic meter of gas – liquid dispersion). The value of a is related to the gas volume fraction or void fraction ε and the *Sauter mean bubble diameter* d_S of the gas. If the gas phase consists of N spherical bubbles of different diameters d, then

$$a = \frac{N \pi \langle d^2 \rangle}{V} \tag{6.198}$$

where $\langle d^2 \rangle$ is the average of the square of the diameters. Similarly, the volume of the gas is

$$\varepsilon V = N \frac{1}{6} \pi \langle d^3 \rangle \tag{6.199}$$

Consequently, the specific contact area a equals

$$a = \frac{6\varepsilon \langle d^2 \rangle}{\langle d^3 \rangle} = \frac{6\varepsilon}{d_S} \tag{6.200}$$

Hence, the Sauter mean diameter d_S of the bubbles follows from

$$d_S = \frac{\sum d^3}{\sum d^2} \tag{6.201}$$

Equation (6.200) shows that a is inversely proportional to the average bubble size of the dispersed gas. This size depends not only on the properties of gas and liquid but also, to a large extent, on the interplay between the mechanisms responsible for the breaking up and mutual coalescence of the bubbles – hence, on reactor hydrodynamics.

Fast Reactions. In the case of a fast reaction in the above reactor ($Ha > 2$), the concentration of A in the liquid bulk $\overline{C_A}$ is zero. Thus, the overall conversion rate — R_A — can be calculated simply by multiplying $\overline{J_A}$ in Equation (6.186) by the total contact area aV between gas and liquid in the reactor:

$$|R_A| V = \sqrt{k \mathbb{D}_A}\, C_{A,i}\, a V \tag{6.202}$$

Slow Reactions. For $Ha < 2$, $\overline{C_A} \neq 0$, so at least part of the reaction takes place in the bulk of the liquid phase. For first-order kinetics a mass balance for A over the *bulk of the liquid phase* gives

In by diffusion through the plane ($x = \delta$) + in by flow – out by flow = consumed by reaction

$$-\mathbb{D}_A \left(\frac{\partial C_A}{\partial x} \right) \Big|_{x=\delta} a V + \varphi_{V0} C_{A0} - \varphi_{V1} \overline{C_A} - k \overline{C_A} (1 - \varepsilon) V = 0 \tag{6.203}$$

where φ_{V0} is the inlet liquid volumetric flow rate (m^3/s), φ_{V1} the outlet liquid volumetric flow rate (m^3/s), and C_{A0} the inlet concentration of

Figure 34. A) Continuous gas – liquid stirred-tank reactor or bubble column; B) Schematic of mass transfer and chemical reaction in such a reactor

reactant A in the liquid (mol/m^3). Because the kinetics are first order, the stagnant film model yields for the concentration gradient at the plane $x=\delta$ (see Eq. 6.176)

$$\left(\frac{\partial C_A}{\partial x}\right)\Big|_{x=\delta} = -C_{A,i}\sqrt{\frac{k}{\mathbb{D}_A}} \cdot \frac{1}{\sinh\left(\delta\sqrt{\frac{k}{\mathbb{D}_A}}\right)} - \frac{\frac{\overline{C_A}}{C_{A,i}}}{\tanh\left(\delta\sqrt{\frac{k}{\mathbb{D}_A}}\right)} \tag{6.204}$$

or by introducing the Hatta number from Equation (6.179)

$$Ha = \frac{\sqrt{k\mathbb{D}_A}}{k_1} = \delta\sqrt{\frac{k}{\mathbb{D}_A}}$$

Equation (6.204) becomes

$$\left(\frac{\partial C_A}{\partial x}\right)\Big|_{x=\delta} = -\sqrt{\frac{k}{\mathbb{D}_A}}\left[\frac{C_{A,i}}{\sinh(Ha)} - \frac{\overline{C_A}}{\tanh(Ha)}\right] \tag{6.205}$$

For convenience the so-called *Hinterland ratio* Al is defined as the ratio between the total liquid phase volume and the volume of the stagnant liquid film:

$$Al = \frac{1-\varepsilon}{a\delta} = \frac{(1-\varepsilon)k_1}{a\mathbb{D}_A} = \frac{1-\varepsilon}{6\varepsilon}\frac{d_S k_1}{\mathbb{D}_A} \tag{6.206}$$

Combination of Equations (6.203), (6.205), and (6.206) yields for $\overline{C_A}$

$$\frac{\overline{C_A}}{C_{A,i}} = \frac{1+\frac{\varphi_{V0}C_{A0}}{\varphi_{V1}C_{A,i}}\frac{1}{k\tau_L}Al\cdot Ha\sinh(Ha)}{\left(\frac{1}{k\tau_L}+\frac{Al-1}{Al}\right)Al\cdot Ha\sinh(Ha)+\cosh(Ha)} \tag{6.207}$$

where τ_L is the residence time of the liquid phase given by $\tau_L = (1-\varepsilon)V/\varphi_{V1}$. Substituting the expression obtained in Equation (6.207) for $\overline{C_A}$ in Equation (6.180) (which gives $\overline{J_A}$ as a function of $\overline{C_A}$) yields

$$\overline{J_A} = k_1 C_{A,i}\cdot Ha\left(\frac{1}{\tanh(Ha)} - \frac{\frac{1}{\sinh(Ha)}+\frac{\varphi_{V0}C_{A0}}{\varphi_{V1}C_{A,i}}\frac{1}{k\tau_L}Al\cdot Ha}{\left(\frac{1}{k\tau_L}+\frac{Al-1}{Al}\right)Al\cdot Ha\sinh(Ha)+\cosh(Ha)}\right) \tag{6.208}$$

Part of A that reaches the bulk of the liquid is converted there (part 1). The remainder leaves the reactor unconverted (part 2). The ratio of (1) over (2) is

$$\frac{k\overline{C_A}(1-\varepsilon)V}{\varphi_{V1}\overline{C_A}} = k\tau_L\left(\frac{Al-1}{Al}\right) \tag{6.209}$$

For an efficient reactor, this ratio must be high; otherwise the reactor woud act more like an absorber or extractor. Therefore, the following assumes that

$$\frac{Al-1}{Al} >> k\tau_L \tag{6.210}$$

Often the amount of A transferred from the gas into the liquid is much higher than the amount

of A introduced into the reactor via the feed of the liquid phase, which means that

$$k_1 C_{A,i} aV >> \varphi_{V0} C_{A0} \tag{6.211}$$

This condition is equivalent to

$$\frac{1}{\sinh(Ha)} >> \frac{\varphi_{V0} C_{A0}}{\varphi_{V1} C_{A,i}} \frac{1}{k\tau_L} Al \cdot Ha \tag{6.212}$$

Substitution of Equations (6.210) and (6.212) in Equations (6.207) and (6.208) gives

$$\frac{\overline{C_A}}{C_{A,i}} = \frac{1}{(Al-1)\, Ha \sinh(Ha) + \cosh(Ha)} \tag{6.213}$$

and

$$\overline{J_A} = \sqrt{k\mathbb{D}_A}\, C_{A,i} \frac{(Al-1)\, Ha + \tanh(Ha)}{(Al-1)\, Ha \tanh(Ha) + 1} \tag{6.214}$$

The above equations hold only if the liquid phase that is fed to or drawn from the reactor contains minor amounts of A compared to the amount of A transferred through the interface.

The enhancement factor E_A (see also Eq. 6.173) can be calculated by combining Equations (6.213) and (6.214):

$$\begin{aligned} E_A &= \frac{\overline{J_A}}{k_l \left(C_{A,i} - \overline{C_A}\right)} \\ &= Ha \frac{(Al-1)\, Ha \cosh(Ha) + \sinh(Ha)}{(Al-1)\, Ha \sinh(Ha) + \cosh(Ha) - 1} \end{aligned} \tag{6.215}$$

For convenience a *degree of reactor utilization* $\eta^{\ominus}$ is defined as the ratio of the conversion rate of A and the highest possible conversion rate that would occur if the entire liquid phase were in equilibrium with the interface (i.e., if $\overline{C_A} = C_{A,i}$). Thus,

$$\eta^{\ominus} = \frac{\overline{J_A}\, aV}{k C_{A,i} (1-\varepsilon) V} \tag{6.216}$$

Note that the degree of reactor utilization is not an effectiveness factor. Substituting Equations (6.213) and (6.214) in (6.216) gives

$$\eta^{\ominus} = \frac{1}{Al \cdot Ha} \frac{(Al-1)\, Ha + \tanh(Ha)}{(Al-1)\, Ha \tanh(Ha) + 1} \tag{6.217}$$

The asymptotic solutions are discussed below.

Slow Reactions. For slow reactions ($Ha < 0.2$) the derived equations simplify to

$$\begin{aligned} \frac{\overline{C_A}}{C_{A,i}} &= \frac{1}{1 + Al \cdot Ha^2} \\ \overline{J_A} &= k_l C_{A,i} \frac{Al \cdot Ha^2}{1 + Al \cdot Ha^2} \\ E_A &= 1 \\ \eta^{\ominus} &= \frac{1}{1 + Al \cdot Ha^2} \end{aligned} \tag{6.218}$$

Mass transfer is not enhanced. Depending on the value of $Al \cdot Ha^2$, the bulk either is saturated with A ($Al \cdot Ha^2 << 1$) or contains A only in relatively low concentration ($Al \cdot Ha^2 >> 1$). The reactor capacity, expressed as moles of A converted per cubic meter of reactor volume and unit time, is given by $J_A\, a$, which, in this case, is equal to $\eta^{\ominus} k C_{A,i} (1-\varepsilon)$ when $Al >> 1$ or the film volume is negligible compared to the bulk volume.

Fast Reactions. For $Ha > 2$, Equations (6.213), (6.215), and (6.217) simplify to

$$\begin{aligned} \frac{\overline{C_A}}{C_{A,i}} &= 0 \\ \overline{J_A} &= \sqrt{k\mathbb{D}_A}\, C_{A,i} \\ E_A &= Ha \\ \eta^{\ominus} &= \frac{1}{Al \cdot Ha} \end{aligned} \tag{6.219}$$

The reactor capacity now becomes independent of the mass-transfer coefficient k_l and of the bulk volume of the liquid phase $(1-\varepsilon)\, V$ because of the absence of reactant in the liquid bulk.

Figure 35. Concentration profiles in hypothetical mass-transfer film (film model) in a bubble column for several combinations of Ha and $Al \cdot Ha^2$
a) $Ha = 5$, any $Al \cdot Ha^2$; b) $Ha = 1$, $Al \cdot Ha^2 = 1000$; c) $Ha = 1$, $Al \cdot Ha^2 = 10$; d) $Ha = 0.1$, $Al \cdot Ha^2 = 1000$; e) $Ha = 0.1$, $Al \cdot Ha^2 = 0.1$

Figure 35 shows concentration profiles for several combinations of Ha and $Al \cdot Ha^2$ to further illustrate the different regimes.

In Figure 36 the degree of reactor utilization $\eta^{\ominus}$ is plotted versus the Hinterland ratio Al for some values of Ha. For a slow reaction ($Ha < 0.2$), the degree of utilization is approximately equal to $1/(1+Al \cdot Ha^2)$ or $\overline{C_A}/C_{A,i}$, as illustrated above. Hence, the degree of utilization approaches unity for $Al \cdot Ha^2 << 1$ and $Ha < 0.2$.

Figure 36. Degree of reactor utilization for simultaneous mass transfer and chemical reaction in a bubble column. In the shaded area more than 80 % of the conversion takes place in the liquid phase.

For a given Hatta number and below a certain value of the Hinterland ratio, say $Al^{\ominus}$, the reactor utilization is 100 % and above that value, $\eta^{\ominus}$ drops below unity. This value $Al^{\ominus}$ decreases with increasing Hatta number. In other words, the faster the reaction is, the larger must the value of the specific contact area be to ensure efficient use of the bulk of the liquid phase.

The Hinterland ratio strongly depends on the (*stirrer*) *specific power input* (i.e., power input per cubic meter of dispersion volume) [39]. The cost of intensive stirring usually exceeds the cost of a larger reactor by far. Therefore, a larger reactor with poor utilization of the liquid bulk is often a cheaper option than a smaller unit that consumes much more energy by intensive stirring. Often the reactor capacity can be increased much more efficiently by an increase in the reaction temperature or reactor pressure, which results in an increase of Ha and $C_{A,i}$ respectively. In that case the influence of temperature on the solubility of A must also be considered.

The above discussions can be summarized for a constant Hatta number as follows. If the degree of reactor utilization approaches 1 ($Ha < 0.2$ and $Al \cdot Ha^2 << 1$), the reactor capacity depends on the volume of the liquid phase and is independent of the value of the specific contact area. If the degree of utilization is much less than 1 ($Ha > 2$ or $Al \cdot Ha^2 >> 1$), the reactor capacity is proportional to the interfacial area and independent of the volume of the liquid phase.

6.2.3.9. Selectivities of Multiple Reactions

In this section the selectivity of *parallel reactions* and *consecutive reactions* is discussed for simultaneous mass transfer and reaction. Although not discussed here, the theory is readily applicable for reactions in porous solids, but the Hatta number must be replaced by the Thiele modulus. The treatment is limited to monomolecular reactions.

Parallel Reactions. Consider the following parallel reaction:

P is again the desired product; X an undesirable byproduct.

For *low Hatta numbers* ($Ha < 0.2$) and a sufficiently large mass-transfer coefficient, so that $\overline{C_A} = C_{A,i}$, selectivity follows from

$$\sigma_{P,Ha<0.2} = \frac{|\mathbb{R}_A\,(C_{A,i})\,|_P}{|\mathbb{R}_A\,(C_{A,i})\,|_P + |\mathbb{R}_A\,(C_{A,i})\,|_X} \tag{6.220}$$

For *high Hatta numbers* ($Ha > 2$) a simple general solution can also be found. In this regime the bulk concentration of A $\overline{C_A}$ equals zero, as discussed above. The penetration depth of A in the liquid δ_p is smaller than the thickness of the stagnant film δ (see Fig. 37). The concentration profile of A can be approximated by a straight line, which is given by

$$C_A = C_{A,i}\,\frac{\delta_p - x}{\delta_p} \tag{6.221}$$

The amount of A that is converted to P in the film, $-R_A-_P$, is determined from

$$|R_A|_P = a\int_0^{\delta_P} |\mathbb{R}_A(C_A)|_P\,\partial x \tag{6.222}$$

Substituting Equation (6.221) gives

$$|R_A|_P = a\frac{\delta_P}{C_{A,i}}\int_0^{C_{A,i}} |\mathbb{R}_A(C_A)|_P\,\partial C_A \tag{6.223}$$

Similarly the amount of A converted in X, $-R_A-_X$, is

$$|R_A|_X = a\frac{\delta_P}{C_{A,i}}\int_0^{C_{A,i}} |\mathbb{R}_A(C_A)|_X\,\partial C_A \tag{6.224}$$

The selectivity $\sigma_P = -R_A-_P/(-R_A-_P + -R_A-_X)$ for high Hatta numbers thus becomes

$$\sigma_{P,Ha>2} = \frac{\int_0^{C_{A,i}} |\mathbb{R}_A(C_A)|_P\,\partial C_A}{\int_0^{C_{A,i}} |\mathbb{R}_A(C_A)|_P\,\partial C_A + \int_0^{C_{A,i}} |\mathbb{R}_A(C_A)|_X\,\partial C_A} \tag{6.225}$$

This equation holds for any arbitrary kinetics and $Ha > 2$.

Figure 37. Concentration profiles (film model) for mass transfer with simultaneous parallel reactions

Consider, for example, the case of n-th- and m-th-order kinetics:

$$|\mathbb{R}_A(C_A)|_P = k_P C_A^n \tag{6.226}$$

$$|\mathbb{R}_A(C_A)|_X = k_X C_A^m \tag{6.227}$$

Equation (6.220) yields for $Ha < 0.2$ and $C_A = C_{A,i}$

$$\sigma_{P,Ha<0.2} = \left(1 + \frac{k_X}{k_P} C_{A,i}^{m-n}\right)^{-1} \tag{6.228}$$

whereas for $Ha > 2$, Equation (6.225) gives

$$\sigma_{P,Ha>2} = \left(1 + \frac{n+1}{m+1}\frac{k_X}{k_P} C_{A,i}^{m-n}\right)^{-1} \tag{6.229}$$

Hence, for $n > m$, $\sigma_{P,\,Ha<0.2} > \sigma_{P,\,Ha>2}$; for $n < m$, $\sigma_{P,\,Ha<0.2} < \sigma_{P,\,Ha>2}$. In other words, if the reaction toward the desired product is of a higher order, mass-transfer limitation decreases the selectivity. If, on the other hand, it is of a lower order, mass-transfer limitation increases the selectivity. Expressions can be derived similarly for other types of kinetics.

Equations (6.220) and (6.225) do not yield a value for selectivity in the intermediate region $0.2 < Ha < 2$. As an approximation for this regime, the authors of this article suggest

$$\sigma_P = \frac{\sigma_{P,\,Ha<0.2} + Ha\,\sigma_{P,\,Ha>2}}{Ha}\cdot\tanh(Ha) \tag{6.230}$$

This approximation can be used only if $\sigma_{P,\,Ha<0.2}$ and $\sigma_{P,\,Ha>2}$ do not differ too much, which usually holds for most practical cases.

Consecutive Reactions. Consider the following consecutive reaction:

$$A \xrightarrow{k_P} \nu_P P \xrightarrow{k_X} \nu_X X$$

Again, P is the desired and X the undesired product. If both reactions are assumed to be first order, the transport equations of A and P become

$$\mathbb{D}_A \frac{\partial^2 C_A}{\partial x^2} = k_P C_A \tag{6.231}$$

$$\mathbb{D}_P \frac{\partial^2 C_P}{\partial x^2} = k_X C_P - \nu_P k_P C_A \tag{6.232}$$

Here $k_P C_A$ is expressed in moles of A per cubic meter per second and $k_X C_P$ is expressed in moles of P per cubic meter per second. Both equations must be solved subject to the boundary conditions

$$\sigma_{\mathrm{P}}=\frac{1}{\beta_1}$$

$$\cdot\left\{1-\frac{\left(Al-1+\frac{\tanh(Ha_{\mathrm{P}})}{Ha_{\mathrm{P}}}\right)\left(\beta_2+\frac{\beta_3+\beta_4}{E_{\mathrm{A0}}}\right)}{\beta_2\left(Al-1+\frac{\tanh(Ha_{\mathrm{P}})}{Ha_{\mathrm{P}}}\right)+\beta_3\left((Al-1)\frac{\tanh(Ha_{\mathrm{P}})}{Ha_{\mathrm{P}}}+\frac{1}{Ha_{\mathrm{P}}^2}\right)}\right\}$$

$x=0\Rightarrow$

$$\mathbb{D}_{\mathrm{A}}\left(\frac{\partial C_{\mathrm{A}}}{\partial x}\right)=k_{\mathrm{g,A}}\left(\overline{C_{\mathrm{A,g}}}-\frac{C_{\mathrm{A,i}}}{m_{\mathrm{A}}}\right)$$

$$\mathbb{D}_{\mathrm{P}}\left(\frac{\partial C_{\mathrm{P}}}{\partial x}\right)=k_{\mathrm{g,P}}\left(\overline{C_{\mathrm{P,g}}}-\frac{C_{\mathrm{P,i}}}{m_{\mathrm{P}}}\right) \tag{6.233}$$

$x=\delta\Rightarrow$

$$a\mathbb{D}_{\mathrm{A}}\left(\frac{\partial C_{\mathrm{A}}}{\partial x}\right)=-(1-\varepsilon)\frac{Al-1}{Al}k_{\mathrm{P}}\overline{C_{\mathrm{A,l}}}$$

$$a\mathbb{D}_{\mathrm{P}}\left(\frac{\partial C_{\mathrm{P}}}{\partial x}\right)=-(1-\varepsilon)\frac{Al-1}{Al}$$

$$\cdot\left(k_{\mathrm{X}}\overline{C_{\mathrm{P,l}}}-\nu_{\mathrm{P}}k_{\mathrm{P}}\overline{C_{\mathrm{A,l}}}\right) \tag{6.234}$$

Furthermore, the mass-transfer coefficients in the liquid phase are related to the film thickness δ as follows

$$k_{\mathrm{l,A}}=\frac{\mathbb{D}_{\mathrm{A}}}{\delta} \tag{6.235}$$

$$k_{\mathrm{l,P}}=\frac{\mathbb{D}_{\mathrm{P}}}{\delta} \tag{6.236}$$

The molar flux of A is obtained by solving the above set of equations [40]:

$$\overline{J_{\mathrm{A}}}=\sqrt{\mathrm{k}\,\mathbb{D}_{\mathrm{A}}}\overline{C_{\mathrm{A,g}}}\left(\frac{1}{\frac{1}{m_{\mathrm{A}}}+E_{\mathrm{A0}}\frac{k_{\mathrm{l,A}}}{k_{\mathrm{g,A}}}}\right) \tag{6.237}$$

where E_{A0} is a modified enhancement factor, defined as

$$E_{\mathrm{A0}}=\frac{\overline{J_{\mathrm{A}}}}{k_{\mathrm{l,A}}C_{\mathrm{A,i}}}=Ha\frac{(Al-1)\,Ha+\tanh(Ha)}{(Al-1)\,Ha\tanh(Ha)+1} \tag{6.238}$$

and

$$Ha=\frac{\sqrt{k_{\mathrm{P}}\mathbb{D}_{\mathrm{A}}}}{k_{\mathrm{l,A}}} \tag{6.239}$$

Compare with Equations (6.164) and (6.214). The selectivity σ_{P} is

$$\beta_1=1-\frac{\mathbb{D}_{\mathrm{A}}}{\mathbb{D}_{\mathrm{P}}}\frac{k_{\mathrm{X}}}{k_{\mathrm{P}}}$$

$$\beta_2=\nu_{\mathrm{P}}m_{\mathrm{P}}\frac{k_{\mathrm{l,P}}}{k_{\mathrm{g,P}}}\frac{k_{\mathrm{P}}}{k_{\mathrm{X}}} \tag{6.240}$$

$$\beta_3=\nu_{\mathrm{P}}\frac{k_{\mathrm{P}}}{k_{\mathrm{X}}}$$

$$\beta_4=\frac{m_{\mathrm{P}}\overline{C_{\mathrm{P,g}}}}{m_{\mathrm{A}}\overline{C_{\mathrm{A,g}}}}\left(\frac{\mathbb{D}_{\mathrm{P}}}{\mathbb{D}_{\mathrm{A}}}\frac{k_{\mathrm{P}}}{k_{\mathrm{X}}}-1\right)$$

Ha_{P} is a modified Hatta number for the consecutive reaction

$$Ha=\frac{\sqrt{k_{\mathrm{X}}\mathbb{D}_{\mathrm{P}}}}{k_{\mathrm{l,P}}} \tag{6.241}$$

Equation (6.240) is simplified considerably if the mass-transfer resistance on the gas-phase side is negligible (i.e., $k_{\mathrm{g,P}}\to\infty$ and $\beta_2\to 0$) and if $\overline{C_{\mathrm{P,g}}}=0$ (thus $\beta_4\to 0$). Then,

$$\sigma_{\mathrm{P}}=\frac{Ha^2}{Ha^2-Ha_{\mathrm{P}}^2}\cdot\left(1-\frac{Ha_{\mathrm{P}}(Al-1)\,Ha\tanh(Ha)+1}{Ha\,(Al-1)\,Ha_{\mathrm{P}}\tanh(Ha_{\mathrm{P}})+1}\cdot\frac{(Al-1)\,Ha_{\mathrm{P}}+\tanh(Ha_{\mathrm{P}})}{(Al-1)\,Ha+\tanh(Ha)}\right) \tag{6.242}$$

Two limiting regimes are mentioned here:

1) In the *slow reaction regime* ($Ha<0.2$ and $Ha_{\mathrm{P}}<0.2$), Equation (6.242) yields

$$\sigma_{\mathrm{P}}=\frac{1}{1+(Al-1)\,Ha_{\mathrm{P}}^2} \tag{6.243}$$

2) In the *fast reaction regime* ($Ha>2$ and $Ha_{\mathrm{P}}>2$), Equation (6.242) yields

$$\sigma_{\mathrm{P}}=\frac{Ha}{Ha+Ha_{\mathrm{P}}} \tag{6.244}$$

In both cases the selectivity is between zero and unity. Of course it follows that $\sigma_{\mathrm{P}}>0$ because of the assumption $\overline{C_{\mathrm{P,g}}}=0$. In the slow reaction regime the interfacial area should be made as

large – and the liquid volume as small – as possible (decrease of Al), which is the case in a foam reactor.

For more complex reaction schemes, expressions for selectivity can be derived in a way similar to that illustrated above. However, the mathematics can become quite involved and tedious.

6.2.4. Reactions of Gases in Liquids – Part II:Reactants from both the Gas and the Liquid

6.2.4.1. Introduction

In this section the following system is discussed:

$$A\,(g) \longrightarrow A\,(l)$$

$$A\,(l) + \nu\,B\,(l) \longrightarrow \text{Products}\,(l)$$

where (g) and (l) refer to the gas and liquid phases, respectively (more generally they refer to phase 1 and phase 2, respectively). Hence, one reactant is transferred from the gas phase to react with a component already present in the liquid phase.

Three limiting cases are possible:

Slow Reaction. The reaction rate is low compared to the rate of mass transfer. Characteristic of this regime is that the rate of mass transfer is not enhanced by the reaction and the reaction proceeds mainly in the bulk of the liquid phase (see Fig. 38).

Figure 38. Concentration profiles (film theory) for reaction between reactants from the gas and liquid phases giving a slow reaction in the bulk of the liquid

Fast Reaction. The rate of reaction is so high compared to the mass-transfer rate that A is completely converted near the interf ace. For this situation the rate of mass transfer is enhanced by the chemical reaction and $\overline{C_A} = 0$ (see Fig. 39).

Figure 39. Concentration profiles (film theory) for reaction between reactants from the gas and liquid phases giving a fast reaction in the film on the liquid side

Instantaneous Reaction. An instantaneous reaction is, in fact, an asymptotic situation of the previous case. Now, the reaction rate is so high that the overall conversion rate is limited completely by diffusion of both A and B into the reaction zone. A and B do not occur at the same place. The place where A and B meet each other is known as the reaction plane in which both C_A and C_B are zero. In this case the enhancement factor E_A reaches its maximum value (see Fig. 40).

Figure 40. Concentration profiles (film theory) for a reaction between reactants from the gas and liquid bulk giving an instantaneous reaction

In the following sections, each case is analyzed in detail. Unless stated otherwise, (1,1)-kinetics are assumed:

$$|\mathbb{R}\,(C_A, C_B)\,| = k_{1,1} C_A\, C_B \tag{6.245}$$

6.2.4.2. Slow Reaction

Here, mass transfer through the interface is not enhanced by reaction. The reaction occurs mainly in the bulk of the liquid phase. This regime is identical to the case in which $Ha < 0.2$ for monomolecular first-order kinetics (see Eq. 6.218), albeit now the pseudo-first-order reaction rate constant k' is given by

$$k' = k_{1,1}\,\overline{C_{\mathrm{B}}} \tag{6.246}$$

so that the Hatta number is defined as

$$Ha = \frac{\sqrt{k'\mathbb{D}_{\mathrm{A}}}}{k_1} = \frac{\overline{k_{1,1}\,\overline{C_{\mathrm{B}}}\mathbb{D}_{\mathrm{A}}}}{k_1} \tag{6.247}$$

Notice that this equation is different from that for (1,1)-kinetics if both reactants are transferred from the gas phase (see Eq. 6.197). Equation (6.247) implies that in reactors where the bulk composition of B depends on the place inside the reactor, Ha is also place dependent. For such reactors the condition $Ha < 0.2$ must be verified to hold everywhere in the reactor.

In line with results obtained in the previous section, the degree of reactor utilization is again given by

$$\eta^{\ominus} = \frac{\overline{C_{\mathrm{A}}}}{C_{\mathrm{A,i}}} = \frac{1}{1 + Al \cdot Ha^2} \tag{6.248}$$

provided only negligible amounts of A enter or leave the reactor with the liquid phase (compared to the amount of A transferred through the interface).

Notice that the case of slow reaction does not exclude a concentration gradient of B in the film (in terms of the stagnant film theory). The above condition $Ha < 0.2$ guarantees a straight-line profile of A in the film (no chemical enhancement of mass transfer for A), but no statement is made about the gradient of B. However, as long as $Al >> 1$, possible concentration gradients of B in the film hardly influence the overall conversion rate because the reaction takes place mainly in the liquid bulk, even at low values of $\overline{C_{\mathrm{A}}}/C_{\mathrm{A,i}}$.

6.2.4.3. Fast Reaction

For $Ha > 2$ – with Ha defined by Equation (6.247) – the reaction takes place exclusively near the interface. In terms of stagnant film theory this means that all reaction occurs in the stagnant film. Thus far, the situation is identical with the previously treated case of first-order reactions with reactants from the gas only. The situation is complicated by the fact that the enhancement factor E_{A} depends on the concentration of B in the film (i.e., by whether diffusion limitation of B occurs in the reaction zone or not). If more than enough B can be supplied to the film, the situation $C_{\mathrm{B}} = \overline{C_{\mathrm{B}}}$ is approached everywhere in the film. Hence, the reaction can be treated as a pseudo-first-order monomolecular reaction with, again, $k' = k_{1,1}\,\overline{C_{\mathrm{B}}}$, so that the Hatta number equals

$$Ha = \frac{\sqrt{k_{1,1}\,\overline{C_{\mathrm{B}}}\mathbb{D}_{\mathrm{A}}}}{k_1} \tag{6.249}$$

and the enhancement factor $E_{\mathrm{A}} = Ha$ because $Ha > 2$.

The criterion determining whether or not this approach is allowed is derived below by using the stagnant film model. The assumption of a constant C_{B} $(= \overline{C_{\mathrm{B}}})$ all over the film is allowed if (see Fig. 41)

$$\frac{\overline{C_{\mathrm{B}}} - C_{\mathrm{B,i}}}{\overline{C_{\mathrm{B}}}} << 1 \tag{6.250}$$

The reaction takes place mainly near the interface in a smaller zone within the stagnant film of thickness δ. The thickness of this smaller reaction zone is denoted by δ_{r}. Its value follows from

$$E_{\mathrm{A}} = \frac{\overline{J_{\mathrm{A}}}}{k_1\left(C_{\mathrm{A,i}} - \overline{C_{\mathrm{A}}}\right)} = -\frac{\mathbb{D}_{\mathrm{A}}\left(\frac{\partial C_{\mathrm{A}}}{\partial x}\right)\Big|_{x=0}}{k_1 C_{\mathrm{A,i}}}$$

$$= \frac{\mathbb{D}_{\mathrm{A}}}{k_1 C_{\mathrm{A,i}}}\frac{C_{\mathrm{A,i}}}{\delta_{\mathrm{r}}} = \frac{\delta}{\delta_{\mathrm{r}}} \Rightarrow \delta_{\mathrm{r}} = \frac{\delta}{E_{\mathrm{A}}} = \frac{\delta}{Ha} \tag{6.251}$$

The conversion rate of B in the reaction zone must equal the transport rate of B from the bulk to the zone $0 < x < \delta_{\mathrm{r}}$. A conservative simplification gives

$$\overline{J_{\mathrm{B}}} \approx \frac{\mathbb{D}_{\mathrm{B}}}{\delta}\left(\overline{C_{\mathrm{B}}} - C_{\mathrm{B,i}}\right) \tag{6.252}$$

Actually $\overline{J_{\mathrm{B}}}$ will be somewhat higher since the slope at $x = \delta$ is higher than the above average slope. For the mole flux of A, Equation (6.251) gives

$$\overline{J_A} = \frac{\mathbb{D}_A}{\delta_r} C_{A,i} = \frac{\mathbb{D}_A}{\delta} C_{A,i}\, Ha \tag{6.253}$$

Combining Equations (6.252) and (6.253) together with $\overline{J_B} = \nu\, \overline{J_A}$ yields

$$\mathbb{D}_B \left(\overline{C_B} - C_{B,i}\right) \approx \nu \mathbb{D}_A C_{A,i}\, Ha \tag{6.254}$$

Thus, from this result, $(\overline{C_B} - C_{B,i})/\overline{C_B} << 1$ for

$$Ha << \frac{\mathbb{D}_B\, \overline{C_B}}{\nu \mathbb{D}_A C_{A,i}} \tag{6.255}$$

Hence, in conclusion,

$$E_A = Ha \text{ for } 2 < Ha << \frac{\mathbb{D}_B\, \overline{C_B}}{\nu \mathbb{D}_A C_{A,i}} \tag{6.256}$$

with Ha according to Equation (6.249).

Figure 41. General concentration profile (film theory) for a reaction between reactants from the gas and liquid phases and $Ha > 2$

If Ha is not much lower than $(\mathbb{D}_B\, \overline{C_B})/(\nu\, \mathbb{D}_A\, C_{A,i})$, diffusion limitation of B occurs, the maximum transport rate of B becomes slow compared to the maximum possible conversion rate of B in the reaction zone, and $C_{B,i}$ becomes lower than $\overline{C_B}$. With increasing value of $Ha \left(\frac{\mathbb{D}_B\, \overline{C_B}}{\nu \mathbb{D}_{A,i} C_{A,i}}\right)^{-1}$, the concentration profile changes from that shown in Figure 42 A to that in Figure 42 D. The last reflects the asymptotic case of an instantaneous reaction. For the case of diffusion limitation of B, E_A will be lower than Ha. This is illustrated in the following section.

6.2.4.4. Instantaneous Reaction

When the reaction rate is very fast compared to the mass-transfer rates of both A and B, the reaction is called instantaneous. Section 6.2.4.4 shows that this is the case for both $Ha > 2$ and

$$Ha >> \frac{\mathbb{D}_B \overline{C_B}}{\nu \mathbb{D}_A C_{A,i}} \tag{6.257}$$

The reaction zone reduces to a plane at $x = \delta_r$: A and B react so fast that they are not found at the same place, except in that plane. In terms of film theory, mass transfer of A and B to the reaction plane is given by (see Fig. 42 D)

$$\overline{J_A} = \frac{\mathbb{D}_A}{\delta_r} C_{A,i} \tag{6.258}$$

$$\overline{J_B} = \frac{\mathbb{D}_B}{\delta_B - \delta_r}\, \overline{C_B} \tag{6.259}$$

Combination with $\overline{J_B} = \nu\, \overline{J}_A$ and elimination of δ_r and $\overline{J_B}$ give

$$\overline{J_A} = \frac{\mathbb{D}_A}{\delta_B} C_{A,i} \left(1 + \frac{\mathbb{D}_B\, \overline{C_B}}{\nu \mathbb{D}_A C_{A,i}}\right) \tag{6.260}$$

The film thickness in this equation, δ_B, is that of component B. To express $\overline{J_A}$ in the mass-transfer coefficient of A, $k_{l,A}$, the film thickness for component A, δ_A, must be introduced:

$$\overline{J_A} = \frac{\mathbb{D}_A}{\delta_A} C_{A,i} \left(1 + \frac{\mathbb{D}_B\, \overline{C_B}}{\nu \mathbb{D}_A C_{A,i}}\right) \left(\frac{\delta_A}{\delta_B}\right) \tag{6.261}$$

or, because the film model is used,

$$\overline{J_A} = k_{l,A}\, C_{A,i} \left(1 + \frac{\mathbb{D}_B\, \overline{C_B}}{\nu \mathbb{D}_A C_{A,i}}\right) \left(\frac{k_{l,B}}{k_{l,A}} \frac{\mathbb{D}_A}{\mathbb{D}_B}\right) \tag{6.262}$$

Hence the enhancement factor E_A, which in this regime is generally referred to as $E_{A\infty}$, follows from

$$E_A \equiv E_{A\infty} = \left(1 + \frac{\mathbb{D}_B\, \overline{C_B}}{\nu \mathbb{D}_A C_{A,i}}\right) \left(\frac{k_{l,B}}{k_{l,A}} \frac{\mathbb{D}_A}{\mathbb{D}_B}\right) \tag{6.263}$$

The ratio $k_{l,A}/k_{l,B}$ generally equals $(\mathbb{D}_A/\mathbb{D}_B)^n$, where the number n depends on the model used or the local hydrodynamics. Thus, in general,

$$E_{A\infty} = \left(1 + \frac{\mathbb{D}_B\, \overline{C_B}}{\nu \mathbb{D}_A C_{A,i}}\right) \left(\frac{\mathbb{D}_A}{\mathbb{D}_B}\right)^{1-n} \tag{6.264}$$

Figure 42. Concentration profiles (film model) for mass transfer with simultaneous irreversible reaction in the liquid phase for a reaction of the order (1,1) with $Ha > 2$ and the following:

A) $Ha << \frac{D_B \overline{C_B}}{v D_A C_{A,i}}$; B) $Ha \approx \frac{D_B \overline{C_B}}{v D_A C_{A,i}}$; C) $Ha \approx 5 \frac{D_B \overline{C_B}}{v D_A C_{A,i}}$; D) $Ha \approx 10 \frac{D_B \overline{C_B}}{v D_A C_{A,i}}$

Higbie's penetration model assumes that the contact time τ of the small stagnant fluid element attached to the interface is an only function of the hydrodynamics and does not depend on physical properties such as the diffusion coefficient $\mathbb{D}$. From this assumption, $k_1 = 2\sqrt{\mathbb{D}/(\pi\tau)} \sim \sqrt{\mathbb{D}}$ (see Eq. 5.26) and hence n in Equation (6.264) equals 1/2.

Generally, the enhancement factor for instantaneous reactions equals, at least to a good approximation [41], [42],

$$E_{A\infty} \approx \left(1 + \frac{\mathbb{D}_B \overline{C_B}}{\nu \mathbb{D}_A C_{A,i}}\right) \left(\frac{\mathbb{D}_A}{\mathbb{D}_B}\right)^{1-n} \tag{6.265}$$

with, e. g.,

$n = 1/2$	Penetration model
$n = 2/3$	Laminar flow
$n = 2/3 - 3/4$	Fully developed turbulent flow

If $\overline{C_B}/(\nu\, C_{A,i})$ is not much larger than unity, the approximation

$$E_{A\infty} \approx 1 + \frac{\mathbb{D}_B \overline{C_B}}{\nu \mathbb{D}_A C_{A,i}} \left(\frac{\mathbb{D}_A}{\mathbb{D}_B}\right)^{1-n} \tag{6.266}$$

is preferred [41].

Theoretically, Fick's law, which is the basis of all derivations discussed above, is applicable only for a plane through which no overall mass flux occurs (e.g., see [1]). Especially for instantaneous reactions, high mass-transfer rates can be obtained and the validity of this assumption becomes questionable. STEPANEK and SHILIMKAN derived a more general equation for the enhancement factor $E_{A\infty}$ for instantaneous reaction, on the basis of the film theory [43]. For the reaction

$$A + \nu_B B \rightarrow \nu_P P + \nu_Q Q$$

they obtained

$$E_{A\infty} = 1 + \frac{1}{\Delta\nu} \frac{\mathbb{D}_B}{\mathbb{D}_A} \frac{\ln\left(1 + \frac{\Delta\nu}{\nu_B} \overline{\kappa}_B\right)}{\ln\left(\frac{1}{1-\kappa_{A,i}}\right)} \tag{6.267}$$

with

$$\Delta\nu = \nu_P + \nu_Q - \nu_B \tag{6.268}$$

where $\kappa_{A,i}$ is the interface mole fraction of A and $\overline{\kappa}_B$ the mole fraction of B in the liquid bulk. For dilute systems (i.e., $\kappa_{A,i}$ and $\overline{\kappa}_B << 1$ with $\kappa_{A,i}$ and $\overline{\kappa}_B \approx C_{A,i}/C$ and $\overline{C_B}/C$, respectively,

since the molar density is constant), Equation (6.267) simplifies to

$$E_{A\infty} \approx 1 + \frac{\mathbb{D}_B \overline{C_B}}{\nu_B \mathbb{D}_A C_{A,i}} \tag{6.269}$$

which resembles Equation (6.266).

6.2.4.5. Van Krevelen – Hoftijzer Approximation

Here a more rigorous general solution is discussed for simultaneous mass transfer and reaction in a liquid with reactants from both the gas and the liquid phases, in which (1,1)-kinetics is assumed. The differential equations describing the reaction and mass transfer near the interface for the stagnant film model state

$$\mathbb{D}_A \frac{\partial^2 C_A}{\partial x^2} - k_{1,1} C_A C_B = 0 \tag{6.270}$$

$$\mathbb{D}_B \frac{\partial^2 C_B}{\partial x^2} - k_{1,1} C_A C_B = 0 \tag{6.271}$$

with the boundary conditions

$$x = 0 \Rightarrow C_A = C_{A,i} \quad \text{and} \quad \frac{\partial C_B}{\partial x} = 0 \tag{6.272}$$

$$x = \delta \Rightarrow C_A = \overline{C_A} \quad \text{and} \quad C_B = \overline{C_B} \tag{6.273}$$

Figure 43. Concentration profile approximation (film model) as suggested by VAN KREVELEN and HOFTIJZER

The boundary condition $\partial C_B/\partial x = 0$ for $x = 0$ states that no B is transferred to the gas phase, meaning that B is not volatile (in gas – liquid systems) or not soluble in the phase where no reaction occurs (if liquid – liquid reactions are considered).

An approximate solution for the above set of equations has been presented by VAN KREVELEN and HOFTIJZER [44]. Their method of approximation has been applied successfully to solve many complex problems in mass transfer with simultaneous reaction. The essence of this method is the approximation of the concentration profile of component B by a constant $C_{B,i}$ over the entire reaction zone (see Fig. 43). The higher the value of δ/δ_r or, according to Equation (6.251), the higher the Hatta number, the better is the approximation. Then, left to the plane $x = \delta_r$, the (1,1)-kinetics reaction becomes pseudo-first order with a rate constant $k' = k_{1,1} C_{B,i}$:

$$|\mathbb{R}(C_A, C_B)| = (k_{1,1} C_{B,i}) C_A \tag{6.274}$$

Hence Equation (6.270) simplifies to

$$\mathbb{D}_A \frac{\partial^2 C_A}{\partial x^2} - (k_{1,1} C_{B,i}) C_A = 0 \tag{6.275}$$

subject to Equations (5.21) and (5.22):

$$x = 0 \Rightarrow C_A = C_{A,i}$$
$$x = \delta \Rightarrow C_A = \overline{C_A}$$

The solution is given by (see Eq. 6.180)

$$\overline{J_A} = k_{l,A} C_{A,i} \frac{Ha_i}{\tanh(Ha_i)} \left(1 - \frac{\overline{C_A}}{C_{A,i}} \frac{1}{\cosh(Ha_i)}\right) \tag{6.276}$$

with Ha_i a *modified Hatta number* based on the interface concentration $C_{B,i}$:

$$Ha_i = \frac{\sqrt{k' \mathbb{D}_A}}{k_l} = \frac{\sqrt{k_{1,1} C_{B,i} \mathbb{D}_A}}{k_l} = Ha \sqrt{\frac{C_{B,i}}{\overline{C_B}}}$$

where

$$Ha = \frac{\sqrt{k_{1,1} C_B \mathbb{D}_A}}{k_l} \tag{6.277}$$

The unknown concentration $C_{B,i}$ is obtained from mass balances. Since $\overline{J_B} = \nu \overline{J_A}$,

$$\frac{\mathbb{D}_B}{\delta - \delta_r} (\overline{C_B} - C_{B,i}) = \nu \frac{\mathbb{D}_A}{\delta_r} (C_{A,i} - \overline{C_A}) \tag{6.278}$$

or

$$\frac{C_{\mathrm{B,i}}}{\overline{C_{\mathrm{B}}}} = 1 - \left(\frac{\delta - \delta_{\mathrm{r}}}{\delta_{\mathrm{r}}}\right) \nu \frac{\mathbb{D}_{\mathrm{A}}}{\mathbb{D}_{\mathrm{B}}} \frac{C_{\mathrm{A,i}} - \overline{C_{\mathrm{A}}}}{\overline{C_{\mathrm{B}}}} \tag{6.279}$$

which for low bulk concentrations $\overline{C_{\mathrm{A}}}$ (high Hatta numbers) reduces to

$$\frac{C_{\mathrm{B,i}}}{\overline{C_{\mathrm{B}}}} = 1 - \left(\frac{\delta - \delta_{r}}{\delta_{\mathrm{r}}}\right) \nu \frac{\mathbb{D}_{\mathrm{A}}}{\mathbb{D}_{\mathrm{B}}} \frac{C_{\mathrm{A,i}}}{C_{\mathrm{B}}} \tag{6.280}$$

An expression for $\delta/\delta_{\mathrm{r}}$ is obtained by defining a *modified enhancement factor* E_{A0} according to

$$\overline{J_{\mathrm{A}}} = -\mathbb{D}_{\mathrm{A}} \left(\frac{\partial C_{\mathrm{A}}}{\partial x}\right)\Big|_{x=0} = \frac{\mathbb{D}_{\mathrm{A}}}{\delta} C_{\mathrm{A,i}} E_{\mathrm{A0}} \tag{6.281}$$

(see Eq. 6.238). For low bulk concentrations $\overline{C_{\mathrm{A}}}$ (thus high Hatta numbers), this yields

$$-\left(\frac{\partial C_{\mathrm{A}}}{\partial x}\right)\Big|_{x=0} = \frac{C_{\mathrm{A,i}}}{\delta_{\mathrm{r}}} = \frac{C_{\mathrm{A,i}}}{\delta} E_{\mathrm{A0}}$$
$$\rightarrow E_{\mathrm{A0}} = \frac{\delta}{\delta_{\mathrm{r}}} \tag{6.282}$$

This should be compared with Equation (6.251) where the same relation was found for E_{A} provided $\overline{C_{\mathrm{A}}} \approx 0$. However, E_{A0} is not identical to the enhancement factor E_{A} ; only for the case in which $\overline{C_{\mathrm{A}}} = 0$ does E_{A0} equal E_{A} . In general,

$$\overline{J_{\mathrm{A}}} = k_{\mathrm{l,A}} C_{\mathrm{A,i}} E_{\mathrm{A0}} = k_{\mathrm{l,A}} \left(C_{\mathrm{A,i}} - \overline{C_{\mathrm{A}}}\right) E_{\mathrm{A}} \tag{6.283}$$

and thus, $E_{\mathrm{A0}} \neq E_{\mathrm{A}}$.

Substituting the relation obtained for $\delta/\delta_{\mathrm{r}}$ by Equation (6.282) in Equation (6.280), gives

$$\frac{C_{\mathrm{B,i}}}{\overline{C_{\mathrm{B}}}} = 1 - (E_{\mathrm{A0}} - 1)\, \nu \frac{\mathbb{D}_{\mathrm{A}}}{\mathbb{D}_{\mathrm{B}}} \frac{C_{\mathrm{A,i}}}{\overline{C_{\mathrm{B}}}} \tag{6.284}$$

Furthermore, by approximating the enhancement factor for instantaneous reaction $E_{\mathrm{A}\infty}$ as in Equation (6.269)

$$E_{\mathrm{A}\infty} \approx 1 + \frac{\mathbb{D}_{\mathrm{B}} \overline{C_{\mathrm{B}}}}{\nu \mathbb{D}_{\mathrm{A}} C_{\mathrm{A,i}}} \tag{6.285}$$

Equation (6.284) becomes

$$\frac{C_{\mathrm{B,i}}}{\overline{C_{\mathrm{B}}}} = \frac{E_{\mathrm{A}\infty} - E_{\mathrm{A0}}}{E_{\mathrm{A}\infty} - 1} \tag{6.286}$$

Notice that this equation was obtained without using the rate equation of —$\mathbb{R}$—: thus Equation (6.286) also applies for reactions with arbitrary kinetics (this is used in Section 6.2.4.6) The parameter Ha_{i} can be expressed in terms of Ha by combining Equations (6.286) and (6.277),

$$Ha_{\mathrm{i}} = Ha \sqrt{\frac{C_{\mathrm{B,i}}}{\overline{C_{\mathrm{B}}}}} = Ha \sqrt{\frac{E_{\mathrm{A}\infty} - E_{\mathrm{A0}}}{E_{\mathrm{A}\infty} - 1}} \tag{6.287}$$

Combining Equations (6.276) and (6.283) yields

$$E_{\mathrm{A0}} = \frac{Ha_{\mathrm{i}}}{\tanh\,(Ha_{\mathrm{i}})} \left(1 - \frac{\overline{C_{\mathrm{A}}}}{C_{\mathrm{A,i}}} \frac{1}{\cosh\,(Ha_{\mathrm{i}})}\right) \tag{6.288}$$

hence,

$$E_{\mathrm{A0}} = \frac{Ha \sqrt{\frac{E_{\mathrm{A}\infty} - E_{\mathrm{A0}}}{E_{\mathrm{A}\infty} - 1}}}{\tanh\left(Ha \sqrt{\frac{E_{\mathrm{A}\infty} - E_{\mathrm{A0}}}{E_{\mathrm{A}\infty} - 1}}\right)} \cdot \left[\left(1 - \frac{\overline{C_{\mathrm{A}}}}{C_{\mathrm{A,i}}}\right) \frac{1}{\cosh\left(Ha \sqrt{\frac{E_{\mathrm{A}\infty} - E_{\mathrm{A0}}}{E_{\mathrm{A}\infty} - 1}}\right)}\right] \tag{6.289}$$

Equation (6.289) is an implicit relation from which the enhancement factor E_{A0} can be obtained by trial and error for any given values of $C_{\mathrm{A,i}}$, $\overline{C_{\mathrm{A}}}$, Ha, and $E_{\mathrm{A}\infty}$. Once E_{A0} is obtained, the molar flux of A through the interface follows from

$$\overline{J_{\mathrm{A}}} = k_{\mathrm{l,A}} C_{\mathrm{A,i}} E_{\mathrm{A0}} \tag{6.290}$$

The three limiting regimes of slow reaction, fast reaction, and instantaneous reaction are all included in Equation (6.289). The accuracy of the approximation is remarkably good: deviation from the exact solution is $< 3\,\%$ according to De Santiago and Farina [45]. Figure 44 presents the solution for $\overline{C_{\mathrm{A}}} = 0$, i.e., for $Al \cdot Ha^2 >> 1$.

Figure 44. Enhancement factor for mass transfer with simultaneous (1,1)-kinetics and for a reaction between reactants from the gas and liquid phases; the figure holds only for $\overline{C_{\mathrm{A}}} = 0$

The above approximation was derived with the aid of the film model. A similar approximation can be derived, for example, from the Higbie penetration model. BRIAN et al. [46] showed that the solutions derived from the penetration and film models are nearly identical.

6.2.4.6. Arbitrary Kinetics

Also for arbitrary kinetics —$\mathbb{R}(C_A, C_B)$— an enhancement factor for mass transfer can be found by applying the Van Krevelen – Hoftijzer approximation. The general principle is always to assume that $C_B \approx C_{B,i}$ in the reaction zone, so the rate equation reduces to

$$|\mathbb{R}(C_A, C_B)| = |\mathbb{R}(C_A, C_{B,i})| \tag{6.291}$$

and is a function only of C_A. Hence, the problem has been reduced to the case of absorption of only one reactant from the gas and arbitrary kinetics, which is treated in Section 6.2.3.7. The Hatta number obtained is a modified one, Ha_i, and is based on $C_{B,i}$ and not on $\overline{C_B}$ like the usual Hatta number Ha. Since Equation (6.286) was derived without using the rate equation, both Hatta numbers can be related by using Equation (6.286)

$$\frac{C_{B,i}}{\overline{C_B}} = \frac{E_{A\infty} - E_{A0}}{E_{A\infty} - 1}$$

As an example, bimolecular reactions with (n,m)-kinetics are discussed:

$$|\mathbb{R}(C_A, C_B)| = k_{n,m} C_A^n C_B^m \tag{6.292}$$

With the Van Krevelen – Hoftijzer assumption, this equation reduces to

$$|\mathbb{R}(C_A, C_B)| = \left(k_{n,m} C_{B,i}^m\right) C_A^n \tag{6.293}$$

and becomes a function of C_A only. The modified Hatta number is derived from (see Eq. 6.190)

$$Ha_i = \frac{\mathbb{D}_A}{k_{l,A}} |\mathbb{R}_A(C_{A,i}, C_{B,i})| \cdot \left[2\mathbb{D}_A \int_0^{C_{A,i}} |\mathbb{R}_A(C_A, C_{B,i})| \partial C_A\right]^{-\frac{1}{2}} \tag{6.294}$$

For pseudo-n-th-order kinetics this becomes (see Eq. 6.192)

$$Ha_i = \frac{\mathbb{D}_A}{k_{l,A}} \sqrt{\frac{n+1}{2} \frac{k_{n,m} C_{A,i}^{n-1} C_{B,i}^m}{\mathbb{D}_A}} \tag{6.295}$$

The enhancement factor E_{A0}, defined according to Equation (6.290)

$$\overline{J_A} = k_{1,A} C_{A,i} E_{A0}$$

can be approximated with Equation (6.183):

$$E_{A0} = \frac{Ha_1}{\tanh(Ha_i)} \tag{6.296}$$

Analogous to Equation (6.277), the true Hatta number is defined as

$$Ha = \frac{\mathbb{D}_A}{k_{l,A}} \sqrt{\frac{n+1}{2} \frac{k_{n,m} C_{A,i}^{n-1} \left(\overline{C_B}\right)^m}{\mathbb{D}_A}} \tag{6.297}$$

so that

$$Ha_i = Ha \sqrt{\left(\frac{E_{A\infty} - E_{A0}}{E_{A\infty} - 1}\right)^m} \tag{6.298}$$

Combination of Equations (6.296) and (6.298) gives

$$E_{A0} = \frac{Ha\sqrt{\left(\frac{E_{A\infty} - E_{A0}}{E_{A\infty} - 1}\right)^m}}{\tanh\left[Ha\sqrt{\left(\frac{E_{A\infty} - E_{A0}}{E_{A\infty} - 1}\right)^m}\right]} \tag{6.299}$$

E_{A0} is obtained from this implicit relation; then the molar flux of A is calculated by using Equation (6.290). Equation (6.299) was first derived by HIKITA and ASAI [47]. The accuracy of this approximation is within 10 %.

For fast reactions and no diffusion limitation of B (see Eq. 6.256),

$$2 < Ha << E_{A\infty} = \frac{\mathbb{D}_B \overline{C_B}}{\nu \mathbb{D}_A C_{A,i}} \tag{6.300}$$

Equation (6.299) reduces to

$$E_{A0} = Ha \tag{6.301}$$

Hence, the conversion rate per cubic meter of dispersion volume follows from

$$|\mathbb{R}_A| = a\overline{J_A} = a k_{l,A} C_{A,i} Ha =$$

$$a\sqrt{\frac{2\mathbb{D}_A k_{n,m}}{n+1}} C_{A,i}^{[(n+1)/2]} \overline{C_B}^{(m/2)} \tag{6.302}$$

Equation (6.302) shows how the apparent reaction orders change, due to diffusion limitation of A. Hence, again mass-transfer limitation can obviously affect the apparent reactant order. Order (0,0) changes to ($\frac{1}{2}$,0); order (1,1), to (1,$\frac{1}{2}$); and (2,2), to ($\frac{3}{2}$,1).

Approximate solutions for (*n,m*)-kinetics by using the Van Krevelen – Hoftijzer assumption with the penetration models have been presented as well. HIKITA and ASAI [47] analyzed the Higbie penetration model; DE COURSEY [48] presented an approximation using the Danckwerts penetration model. The latter is rather practical because an explicit relation is obtained for E_{A0} :

$$E_{A0} = \sqrt{\frac{Ha^4}{4\,(E_{A\infty}-1)^2} + \frac{E_{A\infty}Ha^2}{E_{A\infty}-1} + 1} - \frac{Ha^2}{2\,(E_{A\infty}-1)} \tag{6.303}$$

Differences in accuracy between film and penetration model approximations are negligible. Use of the film model leads to easier derivation of the approximation.

General approximations for other types of kinetics can be derived with the Van Krevelen – Hoftijzer method in a way similar to that illustrated for (*n,m*)-kinetics.

6.2.4.7. Selectivities of Multiple Reactions

The mathematics for the treatment of multiple reactions become quite involved and tedious when reactant is absorbed from the gas whereas the other is already present in the liquid. An extensive overview is given in [8]; only some basic schemes are discussed here.

For mixed parallel – consecutive reactions of the type:

$$A\,(g) \longrightarrow A\,(l)$$

$$A\,(l) + B\,(l) \longrightarrow P\,(l)$$

$$A\,(l) + P\,(l) \longrightarrow X\,(l)$$

numerical and approximated enhancement factors according to stagnant film theory for reaction orders (*n,m*) and (*n′,m′*) respectively, have been presented by ONDA et al. [49]. Numerical and approximated Higbie penetration theory solutions are discussed in [50], [51].

For another type of mixed parallel – consecutive reaction network,

$$A\,(g) \longrightarrow A\,(l)$$

$$A\,(l) + B\,(l) \longrightarrow P\,(l)$$

$$P\,(l) + B\,(l) \longrightarrow X\,(l)$$

enhancement factor calculations have been carried out by BRIAN and BEAVERSTOCK [52] and by RAMACHANDRAN [53].

Simultaneous mass transfer with dependent parallel reactions

$$A_1\,(g) \longrightarrow A_1\,(l)$$

$$A_2\,(g) \longrightarrow A_2\,(l)$$

$$A_1\,(l) + B\,(l) \longrightarrow P\,(l)$$

$$A_2\,(l) + B\,(l) \longrightarrow X\,(l)$$

has been analyzed by GOETTLER and PIGFORD [54], starting from the Higbie penetration theory, and by SHKYLAR et al. [55], starting from the stagnant film model.

Simultaneous absorption followed by a complex consecutive reaction of the type

$$A_1\,(g) \longrightarrow A_1\,(l)$$

$$A_2\,(g) \longrightarrow A_2\,(l)$$

$$A_1\,(l) + B\,(l) \longrightarrow I\,(l) + P\,(l)$$

$$A_2\,(l) + I\,(l) \longrightarrow B\,(l)$$

has been analyzed by ONDA et al. [49].

Finally, the simultaneous absorption of a mixture of phosgene (A_1) and carbon dioxide (A_2) in water to remove phosgene, has the following scheme:

$$A_1\,(g) \longrightarrow A_1\,(l)$$

$$A_2\,(g) \longrightarrow A_2\,(l)$$

$$A_1\,(l) + B\,(l) \longrightarrow A_2\,(l)$$

$$A_2\,(l) + B\,(l) \longrightarrow X\,(l)$$

This system has been analyzed by RAMACHANDRAN and SHARMA [56]. Other, more complex reaction schemes are discussed by WESTERTERP et al. [8].

6.3. Combination of Simultaneous and Series Mass Transfer and Reaction

In all the above cases of mass transfer with simultaneous reaction, the effectiveness factor η and the enhancement factor E_A were written as a function of the interface concentration on the reaction-phase side of the reactants transferred to the reaction phase (e.g., $C_{A,i}$) and of the bulk concentration of the reactants already present in this phase (e.g., $\overline{C_B}$). If *no transfer resistance* of reactants from the nonreaction phase to the interface exists, the interface concentration on the reaction-phase side equals the bulk concentration in the nonreaction phase multiplied by the distribution coefficient m. For example, if the nonreaction phase is a gas and the reaction phase a liquid, for monomolecular reactions with reactant A the following holds:

$$C_{A,i,l} = m C_{A,i,g} = m \overline{C_{A,g}} \tag{6.304}$$

and all equations derived in Sections 6.1 and 6.2 can also be based on gas-phase conditions, provided $C_{A,i,l}$ in the equations is replaced by $m\,\overline{C_{A,g}}$.

If the *transfer resistance of reactants from the bulk of the nonreaction phase is not negligible*, a combination of simultaneous and series mass transfer and reaction can occur: the former in the reaction phase and the latter in the nonreaction phase. A calculation of the overall conversion rate for such cases is shown below. The nonreaction phase is assumed to be the gas phase; the reaction phase might be a porous catalyst pellet or a liquid in which reaction occurs.

For a monomolecular reaction with a reactant A, a mass balance gives

$$\overline{J_A} = k_g \left(\overline{C_{A,g}} - \frac{C_{A,i,l}}{m} \right) = \frac{\eta \left| \mathbb{R}\left(C_{A,i,l}\right) \right|}{a} \tag{6.305}$$

Here a is the specific contact area in square meters of interface area per cubic meter of dispersion volume (e.g., volume of porous pellets plus interstitial gas, or volume of gas bubbles plus liquid bulk). The reaction rate — $\mathbb{R}$ — has the dimension of moles of A per cubic meter of dispersion volume per unit time.

For reactions in porous pellets where $m = 1$, Equation (6.305) reduces to

$$\overline{J_A} = k_g \left(\overline{C_{A,g}} - C_{A,i,g} \right) = \eta \frac{V_p}{A_p} \left| \mathbb{R}\left(C_{A,i,g}\right) \right|_p \tag{6.306}$$

If the concept of an enhancement factor is used instead of the effectiveness factor, Equation (6.305) can be written as (e.g., for gas – liquid systems)

$$\overline{J_A} = k_g \left(\overline{C_{A,g}} - \frac{C_{A,i,l}}{m} \right) = E_A\, k_l\, C_{A,i,l} \tag{6.307}$$

where it is assumed that the reaction phase is a liquid, hence, the index $_l$ in k_l.

The value of η depends only on $C_{A,i,g}$, the reaction kinetics, the size of the catalyst pellet, and (to a lesser extent) the geometry; E_A depends only on $C_{A,i,l}$ and the reaction kinetics. Hence, $C_{A,i,g}$ and $C_{A,i,l}$ can be eliminated from Equations (6.306) and (6.307), respectively, to give the molar flux $\overline{J_A}$ – and thus the overall conversion rate – as a function of $\overline{C_{A,g}}$, the kinetic constants, and the mass-transfer parameters (a, k_g, and $\mathbb{D}_i$; k_g, k_l, and m).

Relatively simple solutions are found for first-order kinetics:

$$\left| \mathbb{R}\left(C_A\right) \right| = k C_A \tag{6.308}$$

In this case, neither the effectiveness factor η nor the enhancement factor E_A depends on the interface concentrations $C_{A,i,g}$ or $C_{A,i,l}$. Hence, Equation (6.306) yields

$$\overline{J_A} = \left(\frac{1}{k_g} + \frac{a}{\eta k} \right)^{-1} \overline{C_{A,g}} \tag{6.309}$$

and from Equation (6.307),

$$\overline{J_A} = \left(\frac{1}{k_g} + \frac{1}{E_A\, m\, k_l} \right)^{-1} \overline{C_{A,g}} \tag{6.310}$$

For arbitrary kinetics, calculations are similar to those above, albeit analytical solutions often cannot be obtained and numerical approximations must be used. Consider for example the case of Langmuir kinetics in a porous catalyst pellet:

$$\left| \mathbb{R}_A \right|_p = \frac{k C_A}{1 + K C_A} \tag{6.311}$$

(see Eq. 6.114). Then the Thiele modulus is found as (see Eq. 6.115):

$$\varphi = \frac{V_p}{A_p} \frac{K C_{A,i,g}}{1 + K C_{A,i,g}} \cdot \sqrt{\frac{k}{2\,\mathbb{D}_{i,A} \left[K C_{A,i,g} - \ln\left(1 + K C_{A,i,g}\right) \right]}} \tag{6.312}$$

The effectiveness factor can be approximated for example by Equation (6.116):

$$\eta = \frac{\tanh(\varphi)}{\varphi}$$

So, Equation (6.306) yields

$$k_g a \left(\overline{C_{A,g}} - C_{A,i,g}\right) = \frac{\tanh(\varphi)}{\varphi} \frac{k C_{A,i,g}}{1 + K C_{A,i,g}} \quad (6.313)$$

Since $C_{A,i,g}$ can be eliminated from Equations (6.312) and (6.313), the conversion rate can be obtained from

$$|\mathbb{R}_A| = \overline{J_A} a = k_g a \left(\overline{C_{A,g}} - C_{A,i,g}\right) \quad (6.314)$$

which gives the conversion rate as a function of $\overline{C_{A,g}}$, k, K, k_g, $\mathbb{D}_{i,A}$, a, and the characteristic pellet dimension V_p/A_p.

Numerical approximations must be used also for bimolecular reactions in general. Again, reaction in a porous catalyst pellet is considered for a reaction $A + \nu B \longrightarrow$ products. Both reactants A and B are supplied from the gas phase. Then, mass balances yield(see Eqs. 6.16, 6.18, and 6.19):

$$\overline{J_A} = k_{g,A} \left(\overline{C_{A,g}} - C_{A,i,g}\right) = \frac{\eta}{a} |\mathbb{R}\left(C_{A,i,g}, C_{B,i,g}\right)| \quad (6.315)$$

and since $\overline{J_B} = \nu \overline{J_A}$,

$$\overline{J_B} = k_{g,B} \left(\overline{C_{B,g}} - C_{B,i,g}\right) = \nu \frac{\eta}{a} |\mathbb{R}\left(C_{A,i,g}, C_{B,i,g}\right)| \quad (6.316)$$

If the excess factor γ is defined as

$$\gamma = \nu \frac{\mathbb{D}_{i,A}}{\mathbb{D}_{i,B}} \frac{C_{A,i,g}}{C_{B,i,g}} \quad (6.317)$$

the Thiele modulus is found from (see Eq. 6.123)

$$\varphi = \frac{V_p}{A_p} |\mathbb{R}\left(C_{A,i,g}, C_{B,i,g}\right)| \left(2\mathbb{D}_{i,A} \int_0^{C_{A,i,g}} |\mathbb{R} \cdot \left\{C_A, C_{B,i,g}\left[1 - \gamma\left(1 - C_A/C_{A,i,g}\right)\right]\right\}| \partial C_A\right)^{-\frac{1}{2}} \quad (6.318)$$

Finally, for the effectiveness factor an approximation can again be used (e.g., Eq. 6.116):

$$\eta = \frac{\tanh(\varphi)}{\varphi}$$

From Equations (6.116) and (6.315)–(6.318), the concentrations $C_{A,i,g}$ and $C_{B,i,g}$ can be eliminated to yield the conversion rate $\overline{J_A}\, a$ as a function of, for example, $\overline{C_{A,g}}$ and $\overline{C_{B,g}}$.

Generalizations like those illustrated above for the effectiveness factor η can be made in a similar way for the enhancement factor E_A.

7. Macrokinetics: Multiphase Systems – Part III: Mass and Heat Transfer with Reaction

7.1. Introduction

Heat effects occur in all chemical reactions. Either heat is produced and the reaction is said to be exothermic or heat is consumed and the reaction is endothermic. These heat effects can influence the temperature of the reaction mixture and, therefore, the chemical reaction rate and the overall conversion rate.

Consequently, for macrokinetic phenomena, apart from mass transfer, heat-transfer resistance can also play a significant role in the overall conversion rate. In this section, the effect of heat-transfer resistance in combination with mass-transfer resistance is discussed. The discussion is limited to the case in which the temperature dependence of the reaction rate is of the Arrhenius type and the physical properties (e.g., specific heat and density, mass and heat transport parameters) can be assumed to be independent of temperature.

Heat and mass transfer and chemical reaction can occur in series or simultaneously, as is the case for only mass transfer with chemical reaction. Both cases are discussed below.

7.2. Mass and Heat Transfer with Reaction in Series

Mass and heat transfer and chemical reaction in series are most relevant for chemical reactions in and on catalyst pellets. Here discussion is limited to heterogeneously catalyzed reactions in the gas phase. It is assumed that either a chemical reaction occurs at the outer surface of the pellet or that intra particle heat- and mass-transfer resistances are negligible. Furthermore, only monomolecular first-order kinetics are treated.

7.2.1. Particle Mass and Heat Balances

For first-order reactions A → products, carried out in or on a catalyst pellet, the overall mass and heat balances for the pellet yield a *mass balance* of:

$$k_g A_p \left(\overline{C_{A,g}} - C_{A,p}\right) = k_p (T_p) C_{A,p} V_p \tag{7.1}$$

and a *heat balance* of:

$$\alpha_g A_p \left(T_p - \overline{T_g}\right) = k_p (T_p) C_{A,p} (-\Delta H_r) V_p \tag{7.2}$$

Here $\overline{C_{A,g}}$ is the concentration of reactant A in the bulk of the gas phase and $C_{A,p}$ its concentration inside the pellet or at the pellet outer surface (since intra particle mass transfer is negligible, the two of them are equal); $\overline{T_g}$ is the temperature of the bulk of the gas and T_p the pellet temperature; $k_p(T_p)$ is the reaction rate constant at pellet temperature T_p; the reaction rate $k_p(T_p) C_{A,p}$ is defined as moles of A converted per cubic meter of catalyst volume per unit time; $(-\Delta H_r)$ is the reaction enthalpy (J/mol) and is positive for exothermic and negative for endothermic reactions; A_p and V_p are the outer surface area and the volume of the pellet, respectively; k_g is the *mass-transfer coefficient* of reactant A (m/s); and α_g is the *heat-transfer coefficient* of the pellet, (W m^{-2} K^{-1}). The heat-transfer coefficient α_g is defined in a manner similar to the mass-transfer coefficient k_g. The latter is the mole flux of A, J_A (moles of A per square meter of external surface area per unit time) divided by the driving force $\overline{C_{A,g}} - C_{A,p}$:

$$k_g = \frac{J_A}{\overline{C_{A,g}} - C_{A,p}} \tag{7.3}$$

Similarly, the heat-transfer coefficient α_g equals the heat flux from or to the pellet ψ'' (joules per square meter of external surface area per unit time) divided by the driving force $T_p - \overline{T_g}$:

$$\alpha_g = \frac{\psi''}{T_p - \overline{T_g}} \tag{7.4}$$

Both transfer coefficients are related by the *Chilton – Colburn analogy*:

$$\frac{\alpha_g}{k_g} = \varrho_g C_{p,g} Le^{2/3} \tag{7.5}$$

where ϱ_g (kg/m^3) is the density of the gas, $C_{p,g}$ (J kg^{-1} K^{-1}) its specific heat, and *Le* the *Lewis number* defined as

$$Le = \frac{a_g}{\mathbb{D}_{A,g}} \tag{7.6}$$

where a_g is the thermal diffusion coefficient of the gaseous bulk phase (m^2/s) and $\mathbb{D}_{A,g}$ (m^2/s) the molecular diffusion coefficient of A in the gas.

For convenience, the pellet concentration $C_{A,p}$ and the heat-transfer coefficient α_g are eliminated from Equations (7.1), (7.2), and (7.5). Then,

$$\frac{T_p - \overline{T_g}}{\Delta T_{ad}} = \left\{1 + \frac{k_g A_p}{k_p (T_p) V_p}\right\}^{-1} Le^{2/3} \tag{7.7}$$

with ΔT_{ad} the adiabatic temperature rise given by

$$\Delta T_{ad} = \frac{\overline{C_{A,g}} (\Delta H_r)}{\varrho_g C_{p,g}} \tag{7.8}$$

If the reaction rate is very fast compared to the rate of mass transfer, or $k_p(T_p) V_p >> k_g A_p$, the pellet operates in the *fast reaction regime* and its temperature reaches the maximum value:

$$T_{p,max} = \overline{T_g} + \Delta T_{ad} Le^{-2/3} \tag{7.9}$$

If the mass-transfer rate is much higher than the reaction rate, $k_p(T_p) V_p << k_g A_p$, the pellet operates in the *slow reaction regime* and its temperature equals the gas temperature. In that case the heat-transfer rate is also relatively fast according to the Chilton – Colburn analogy.

The following dimensionless numbers are also introduced for convencience:

$$\theta_p = \frac{T_p}{\Delta T_{ad}} Le^{2/3} \tag{7.10}$$

$$\theta_g = \frac{\overline{T_g}}{\Delta T_{ad}} Le^{2/3} \tag{7.11}$$

$$\xi(\theta_p) = \frac{k_g A_p}{k_p \left(\Delta T_{ad} Le^{-2/3} \theta_p\right) V_p} \tag{7.12}$$

Substitution of the above numbers in Equation (7.7) gives

$$\theta_p - \theta_g = \frac{1}{1 + \xi(\theta_p)} \tag{7.13}$$

Further, the assumption is made that the mass-transfer coefficient k_g is temperature independent and that the dependence of the reaction rate

constant $k_p(T_p)$ on temperature is of the Arrhenius type:

$$k_p(T_p) = k_{p,0} \exp\left(-\frac{E_a}{RT_p}\right) \tag{7.14}$$

Figure 45. Relative heat production and heat withdrawal rates versus dimensionless pellet temperature ϑ_p
A) Exothermic reactions, θ_p, θ_g, $An > 0$; B) Endothermic reactions, θ_p, θ_g, $An < 0$
● = Stable operating point; ○ = Unstable operating point

Substitution in Equation (7.12) gives

$$\zeta(\vartheta_p) = \xi_0 \exp\left(\frac{An}{\vartheta_p}\right) \tag{7.15}$$

with

$$\xi_0 = \frac{k_g A_p}{k_{p,0} V_p} \tag{7.16}$$

An is a modified *Arrhenius number* defined as

$$An = \frac{E_a}{\Delta T_{ad} R} Le^{2/3} \tag{7.17}$$

An is the dimensionless ratio of the activation temperature E_a/R and the maximum temperature difference between the pellet and the gas (see Eq. 7.9). Substituting Equation (7.15) into Equation (7.13) yields

$$\theta_p - \theta_g = \left[1 + \xi_0 \exp\left(\frac{An}{\theta_p}\right)\right]^{-1} \tag{7.18}$$

From this equation, θ_p and thus T_p can be obtained for any given values of θ_g, ξ_0, and *An*. After calculation of $k_p(T_p)$, Equation (7.1) yields $C_{A,p}$, and hence the conversion rate $k_p(T_p)\, C_{A,p}$ is obtained.

7.2.2. Particle Multiplicity

The right-hand term of Equation (7.18) is a dimensionless pellet heat production rate (HPR) scaled between 0 and 1, being the ratio of the actual to the maximum possible heat production rate. The left-hand term can be regarded as a dimensionless pellet heat withdrawal rate (HWR).

If the left- and right-hand terms of Equation (7.18) are plotted separately versus θ_p, figures such as Figure 45 are obtained. The dimensionless HPR curve is sigmoidal because of the following: At low particle temperatures the system is in the *slow reaction regime;* hence the conversion rate equals the reaction rate. In this regime the conversion rate and thus the heat production rate are low. As pellet temperature increases, the conversion rate and thus HPR initially increase with temperature according to the assumed Arrhenius relation. If the pellet temperature becomes still higher, above a certain temperature the reaction rate is so high that mass transfer becomes rate limiting. The pellet then operates in the *fast reaction regime*, and the overall conversion rate equals the mass-transfer rate. Since mass transfer is virtually independent of temperature, in this regime the HPR does not increase further with increasing pellet temperature; it becomes constant.

The heat withdrawal rate equation is given by $\theta_p - \theta_g$, which is represented by a straight line with a slope of unity and an intercept with the θ_p-axis equal to θ_g.

For *exothermic reactions* ΔT_{ad} and thus also θ_p, θ_g, and *An* are positive. Depending on the parameter values, either one, two, or three operating points are obtained: that is, for the same values of θ_g, *An*, and ξ_0, one, two, or three values can be found for θ_p. This means that in Figure 45, one, two, or three intersection points between the HPR curve and the HWR line are obtained. The occurrence of more than one operating point for the same set of independent parameters is referred to as *multiplicity of steady states*.

For *endothermic reactions*, ΔT_{ad} is negative and hence θ_p, θ_g, and *An* are also. As a result, only a single operating point can be obtained (see Fig. 45), which means that for fixed values of θ_g, *An*, and ξ_0 the value of θ_p is also fixed. Thus for endothermic reactions, multiplicity can not occur.

Multiplicity of Steady States. If the heat withdrawal rate is represented by the line for $\theta_g = 0.3$ in Figure 45, the catalyst pellet is so effectively cooled by the surrounding gas that stable operation is possible only at low temperature and a low conversion rate. If the temperature of the gas is increased much further (e.g., as shown by the line for $\theta_g = 0.7$), cooling of the pellet is so ineffective that operation is possible only at high temperature and a relatively high conversion rate. For intermediate gas temperatures (e.g., the line given for $\theta_g = 0.5$) an HWR line is obtained that has three points of intersection with the heat production curve. For this situation, multiplicity occurs.

In case of multiplicity, of the three intersection points only those at the lowest and highest pellet temperature represent stable conditions: they are therefore called the *stable operating points*. The intermediate intersection point is referred to as an *unstable operating point*.

The stability of these points is determined by the slope of the HPR curve at the point of intersection with the HWR line. For the stable operating points its slope is less than 1, the slope of the HWR line. Therefore, if the temperature of the pellet increases somewhat, more heat is removed than is produced, which implies that the pellet temperature must decrease and thus return to the steady-state value. Similarly, a slightly too low pellet temperature causes more heat to be produced than removed, so the temperature increases. At the intermediate intersection point, on the other hand, the situation is reversed: the slope of the heat production curve is higher than unity. If the pellet temperature becomes slightly too high, more heat is produced than removed, and the pellet temperature increases further until the upper stable operating point is reached. Similarly, if the pellet temperature is a little too low, more heat is removed than produced and the temperature decreases further until the lower stable operating point is reached. So the intermediate operating point must be an unstable one.

In Figure 46, several heat production rate curves and one heat withdrawal rate line are plotted versus the dimensionless pellet temperature θ_p. The parameter values are $An = 3$ and $\theta_g = 0.3$, whereas ξ_0 is varied. Initially $\xi_0 = 0.1$, and the pellet conversion rate is low. Then the gas velocity is decreased. Subsequently the mass-transfer coefficient k_g decreases and thus ξ_0 (see Eq. 7.16). For $\xi_0 = 0.024$ a critical ξ_0 value is passed and the region of multiplicity begins. This multiplicity is illustrated in Figure 46 for $\xi_0 = 0.01$. The pellet remains at the lower stable operating point, until ξ_0 is decreased further to $\xi_0 = 0.0035$. Then the pellet is forced to leave the lower stable operating point and jumps to the higher stable operating point; this switch of operating points is sudden. The pellet is said to exhibit *runaway* or, alternatively, *ignition* of the pellet occurs. The pellet temperature in Figure 46 switches from $\theta_p = 0.34$ *to* $\theta_p = 1.26$. If ξ_0 is further decreased the pellet simply remains at the higher stable operating point, as illustrated for $\xi_0 = 0.001$.

If the velocity and thus ξ_0 are increased again, the pellet reenters the region of multiplicity for $\xi_0 = 0.0035$. In this case the pellet remains at the higher stable operating point until $\xi_0 = 0.024$ is reached. Then the pellet is forced to switch suddenly to the lower operating point. This phenomenon is referred to as *blowout*, or the reaction in the pellet is said to be *extinguished*. For the example given, the pellet temperature drops from $\theta_p = 0.86$ to $\theta_p = 0.30$.

For decreasing ξ_0 values a different line is found than for increasing ξ_0 values as shown in Figure 47. This is referred to as *hysteresis*. Hys-

Figure 46. Relative heat production rate curves versus dimensionless pellet temperature θ_p for $An = 3$, $\theta_g = 0.3$, and several values of ξ_0
a) $\xi_0 = 0.001$; b) $\xi_0 = 0.0035$; c) $\xi_0 = 0.01$; d) $\xi_0 = 0.024$; e) $\xi_0 = 0.1$

teresis is commonly encountered when multiplicity of steady states is important.

Figure 47. Dimensionless pellet temperature θ_p versus ξ_p for $An = 3$ and $\theta_g = 0.3$
Note the hysteresis, runaway, and blowout

The critical values of ξ_0 for runaway and blowout, $\xi_{0,\mathrm{ra}}$ and $\xi_{0,\mathrm{bo}}$, can be found by solving Equation (7.18) together with

$$\frac{\partial}{\partial \theta_p}\left[1+\xi_0 \exp\left(\frac{An}{\theta_p}\right)\right]^{-1} = 1 \tag{7.19}$$

for which case the HPR curve touches the HWR line. Solving Equations (7.18) and (7.19) and eliminating θ_p gives

$$\xi_{0,\mathrm{bo}} = \frac{2 + 2\theta_g + An - \sqrt{An\left(An - 4\theta_g - 4\theta_g^2\right)}}{An - 2\theta_g + \sqrt{An\left(An - 4\theta_g - 4\theta_g^2\right)}} \cdot \exp\left(-\frac{2An\,(1+An)}{An + 2\theta_g An + \sqrt{An\left(An - 4\theta_g - 4\theta_g^2\right)}}\right) \tag{7.20}$$

and

$$\xi_{0,\mathrm{ra}} = \frac{2 + 2\theta_g + An + \sqrt{An\left(An - 4\theta_g - 4\theta_g^2\right)}}{An - 2\theta_g - \sqrt{An\left(An - 4\theta_g - 4\theta_g^2\right)}} \cdot \exp\left(-\frac{2An\,(1+An)}{An + 2\theta_g An - \sqrt{An\left(An - 4\theta_g - 4\theta_g^2\right)}}\right) \tag{7.21}$$

The above equations are useful in the design of packed-bed reactors. For highly exothermic reactions, adiabatic temperature increases are on the order of 1000 – 2000 °C, which implies that at the higher operating point the catalyst temperature is so high that the catalyst would be destroyed. On the other hand, increasing the pellet size is economically attractive, so as to decrease the pressure drop over the packed bed and therefore the costs of compression. However, with increasing particle size the value of ξ_0 decreases and therefore the runaway limit given by Equation (7.21) is approached. Since runaway cannot be allowed, Equation (7.21) gives the maximum tolerable particle size for a given reaction, a given gas temperature, and a given gas velocity.

In Figure 48, $\xi_{0,\,\mathrm{ra}}$ is plotted versus θ_g for several values of *An*. A multiplicity and a uniqueness region can be distinguished. In this last region the slope in the point of inflection of the HPR curve is lower than that of the HWR line, which is 1, so multiplicity can never occur. To find the boundary line mentioned, Equation (7.18) must be solved together with Equations (7.19), and

$$\frac{\partial^2}{\partial\theta_\mathrm{p}^2}\left[1+\xi_0\exp\left(\frac{An}{\theta_\mathrm{p}}\right)\right]^{-1}=0 \tag{7.22}$$

which states that the derivative of the HPR curve is unity at the inflection point. Solving Equations (7.18), (7.19), and (7.22) and eliminating θ_p and *An* give

$$\xi_0=\frac{1+\theta_\mathrm{g}}{\theta_\mathrm{g}}\,\mathrm{e}^{-2(1+\theta_\mathrm{g})} \tag{7.23}$$

This is the boundary line equation giving the dashed line in Figure 48.

Figure 48. Value of $\xi_{0,\,\mathrm{ra}}$ for which runaway occurs versus dimensionless gas temperature θ_g

All pellets in a reactor cannot always be in the uniqueness region. Then, one must ensure that all pellets work at the lower operating point (see Fig. 47). As WESTERTERP et al. have shown, $k_\mathrm{g}\approx\sqrt{u/d_\mathrm{p}}$ with d_p, the particle diameter equivalent to a sphere, $d_\mathrm{p}=6\,V_\mathrm{p}/A_\mathrm{p}$. Thus, $\xi_{0,\,\mathrm{ra}}\sim u^{0.5}\,d_\mathrm{p}^{-1.5}$ [8]. Once the particle diameter has been fixed and safe operating conditions have been chosen for the design (e.g., in Fig. 48, the point given by $\theta_\mathrm{g}=0.3$ and $\xi_0=0.07$, see also Figs. 46 and 47), the diagram can be used further to determine operating adjustments. For example, lowering the throughput to 25 % of its design value would surely lead to (near) runaway, because now

$$\xi_{0,\,\mathrm{new}}=\xi_{0,\,\mathrm{old}}\cdot\sqrt{u_\mathrm{new}/u_\mathrm{old}}=0.5\xi_{0,\,\mathrm{old}}$$
$$=0.035.$$

In the first instance, θ_g should be lowered to prevent pellet runaway. This may lead to too low a temperature and hence too low a conversion. In this case the reactant concentration in the feed may be decreased to increase *An*, so that θ_g can be increased again to achieve sufficiently high reaction rates.

This reasoning also indicates the importance of gas flow rates. If, for example, in a tube of a multitubular reactor, a deposit is formed that decreases the gas velocity because of plugging, at some point pellet runaway will occur irreparably and, consequently, full runaway of that tube [57].

Multiplicity studies for other reaction kinetics proceed along the same lines, albeit simple analytical solutions often cannot be obtained, so numerical approximations must be used.

7.3. Mass and Heat Transfer with Simultaneous Reaction

Due to the heat effects of the reaction, the temperature in the reaction phase (e.g., a catalyst pellet) is not necessarily uniform. Mass and heat transfer with simultaneous reaction therefore must also be studied.

The effect of temperature gradients in the reaction phase can be incorporated readily into the Thiele modulus or Hatta number. In what follows, this will be derived for a porous pellet with intra particle temperature gradients. Extensions to gas – liquid reactions and Hatta numbers can, of course, be made; if, in the Thiele modulus, the characteristic dimension $V_\mathrm{p}/A_\mathrm{p}$ is replaced by $\mathbb{D}_\mathrm{A}/k_{\mathrm{l,\,A}}$ and the effective diffusion coefficient $\mathbb{D}_{\mathrm{i,\,A}}$ by $\mathbb{D}_\mathrm{A}$, the corresponding Hatta numbers are obtained. To simplify the Thiele modulus equations, the Frank-Kamenetzki approximation will be discussed first.

7.3.1. Frank – Kamenetzki Approximation

Consider a monomolecular reaction $A \longrightarrow products$ inside a porous catalyst pellet. By combining microscale mass and heat balances, the relation between the local temperature inside the pellet and the local reactant concentration can be found:

$$\frac{T-T_{\mathrm{i}}}{T_{\mathrm{i}}}=\mu\frac{C_{\mathrm{A,i}}-C_{\mathrm{A}}}{C_{\mathrm{A,i}}} \tag{7.24}$$

with

$$\mu=\frac{(-\Delta H_{\mathrm{r}})\,\mathbb{D}_{\mathrm{i,A}}\,C_{\mathrm{A,i}}}{\lambda_{\mathrm{p}}\,T_{\mathrm{i}}} \tag{7.25}$$

where T is the local temperature and C_{A} the local reactant concentration inside the pellet; T_{i} and $C_{\mathrm{A,i}}$ are the same quantities at the pellet external surface; $(-\Delta H_{\mathrm{r}})$ is the reaction enthalpy (J/mol); $\mathbb{D}_{\mathrm{i,A}}$ the effective diffusion coefficient (m^2/s); and λ_{p} the thermal conductivity of the pellet ($\mathrm{W\,m^{-1}\,K^{-1}}$). Notice that μ can be both positive [for $(-\Delta H_{\mathrm{r}})>0$, thus exothermic reactions] and negative [for $(-\Delta H_{\mathrm{r}})<0$, thus endothermic reactions].

The most extreme temperature T_{ext} is found for $C_{\mathrm{A}}=0$ (i.e., in the center of the pellet and for low effectiveness factors). This extreme temperature can be obtained from

$$\mu=\frac{T-T_{\mathrm{ext}}}{T_{\mathrm{ext}}} \tag{7.26}$$

If the temperature dependence of a reaction rate constant k or adsorption constant K is of the Arrhenius type, according to the above equation,

$$\frac{k\,(T_{\mathrm{i}})}{k\,(T)}=\frac{K\,(T_{\mathrm{i}})}{K\,(T)}=\exp\left[\chi\frac{1-C_{\mathrm{A}}/C_{\mathrm{A,i}}}{1+\mu\left(1-C_{\mathrm{A}}/C_{\mathrm{A,i}}\right)}\right] \tag{7.27}$$

with

$$\chi=\frac{E_{\mathrm{a}}}{RT_{\mathrm{i}}}\,\frac{(-\Delta H_{\mathrm{r}})\,\mathbb{D}_{\mathrm{i,A}}C_{\mathrm{A,i}}}{\lambda_{\mathrm{p}}\,T_{\mathrm{i}}} \tag{7.28}$$

where $k\,(T_{\mathrm{i}})$ is the reaction rate constant and $K\,(T_{\mathrm{i}})$ the adsorption constant at the outer surface temperature. Like μ, χ can also have both positive and negative values.

Equation (7.27) can be simplified if the following assumption holds:

$$\mu\left(1-C_{\mathrm{A}}/C_{\mathrm{A,i}}\right)<<1 \tag{7.29}$$

then,

$$\frac{k\,(T_{\mathrm{i}})}{k\,(T)}=\frac{K\,(T_{\mathrm{i}})}{K\,(T)}=\exp\left[\chi\left(1-C_{\mathrm{A}}/C_{\mathrm{A,i}}\right)\right] \tag{7.30}$$

Table 1. Comparison of χ, μ, and Δ_{FK} values for typical industrial processes [58]

Process	χ	μ	Δ_{FK}, %
Ethylene hydrogenation	0.038	0.0029	0.01
Benzene hydrogenation	0.48	0.030	1
Methane oxidation	0.12	0.0056	0.07
Ethylene oxidation	0.92	0.068	6
Naphthalene oxidation	0.33	0.015	0.5
Acrylonitrile synthesis	0.018	0.0019	0.003

Figure 49. Effectiveness factor η versus Thiele modulus φ for first-order kinetics in an infinite slab and with significant intra particle temperature gradients (several values of χ have been assumed
a) $\chi=-\infty$; b) $\chi=0$; c) $\chi=+2$; d) $\chi=+4$; e) $\chi=+6$; f) $\chi=+8$

Equation (7.29) is generally referred to as the *Frank – Kamenetzki approximation*. Basically this assumption means that the Arrhenius-type dependence of reaction rates and adsorption constants can be approximated by an exponential relationship.

Comparison of Equations (7.27) and (7.30) shows that the error Δ_{FK} introduced by using the Frank – Kamenetzki approximation equals

$$\Delta_{\mathrm{FK}} = \left| \frac{\exp\left[\chi \frac{1 - C_{\mathrm{A}}/C_{\mathrm{A,i}}}{1+\mu\left(1-C_{\mathrm{A}}/C_{\mathrm{A,i}}\right)}\right] - \exp\left[\chi\left(1 - C_{\mathrm{A}}/C_{\mathrm{A,i}}\right)\right]}{\exp\left[\chi \frac{1-C_{\mathrm{A}}/C_{\mathrm{A,i}}}{1+\mu\left(1-C_{\mathrm{A}}/C_{\mathrm{A,i}}\right)}\right]} \right|$$

$$= \exp\left[\mu\chi \frac{\left(1 - C_{\mathrm{A}}/C_{\mathrm{A,i}}\right)^2}{1+\mu\left(1 - C_{\mathrm{A}}/C_{\mathrm{A,i}}\right)}\right] - 1 \tag{7.31}$$

The largest value of Δ_{FK} is found for $C_{\mathrm{A}} = 0$; hence for low effectiveness factors and in the pellet center,

$$\Delta_{\mathrm{FK,\,max}} = \exp\left(\chi \frac{\mu}{1+\mu}\right) - 1 \tag{7.32}$$

In Table 1, values are given for χ, μ, and $\Delta_{\mathrm{FK,\,max}}$ for some typical industrial processes [58]. $\Delta_{\mathrm{FK,\,max}}$ is generally very small and $< 10\,\%$ for all cases. Hence, the Frank – Kamenetzki approximation can be used without introducing significant error.

7.3.2. Thiele Moduli and Hatta Numbers

The temperature inside the catalyst pellet can be related to the concentration of reactant A as (see Eq. 7.24)

$$T = T_{\mathrm{i}}\left[1+\mu\left(1-C_{\mathrm{A}}/C_{\mathrm{A,\,i}}\right)\right] \tag{7.33}$$

Hence the reaction rate, which generally is a function of both the temperature T and the concentration C_{A}, can be written as a function of the concentration only:

$$|\mathbb{R}\left(C_{\mathrm{A}}, T\right)| = |\mathbb{R}\left\{C_{\mathrm{A}}, T_{\mathrm{i}}\left[1+\mu\left(1-C_{\mathrm{A}}/C_{\mathrm{A,\,i}}\right)\right]\right\}| \tag{7.34}$$

Consequently, a general definition of the Thiele modulus for monomolecular reactions with arbitrary kinetics and significant intra particle temperature gradients follows from (see Eq. 6.123):

$$\varphi = \frac{V_{\mathrm{p}}}{A_{\mathrm{p}}} |\mathbb{R}_{\mathrm{A}}\left(C_{\mathrm{A,\,i}}, T_{\mathrm{i}}\right)|_{\mathrm{p}} \left(2\mathbb{D}_{\mathrm{i,\,A}} \int_0^{C_{\mathrm{A,\,i}}} |\mathbb{R}_{\mathrm{A}} \cdot \left\{C_{\mathrm{A}}, T_{\mathrm{i}}\left[1+\mu\left(1-C_{\mathrm{A}}/C_{\mathrm{A,\,i}}\right)\right]\right\}|_{\mathrm{p}} \partial C_{\mathrm{A}}\right)^{-\frac{1}{2}} \tag{7.35}$$

In solving the above equations for any form of kinetics, use of the Frank – Kamenetzki approximation for the reaction rate and adsorption constants is advisable (i.e., assume an exponential instead of an Arrhenius-type temperature dependence). For example, for n th-order kinetics, use of Equation (6.191)

$$|\mathbb{R}\left(C_{\mathrm{A}}\right)| = kC_{\mathrm{A}}^n$$

with the Frank – Kamenetzki approximation Equation (7.35) yields

$$\varphi = \frac{V_{\mathrm{p}}}{A_{\mathrm{p}}} \int \sqrt{\frac{k\left(T_{\mathrm{i}}\right) C_{\mathrm{A,\,i}}^{n-1}}{2\mathbb{D}_{\mathrm{i,\,A}}} \left(\mathrm{e}_0^{\chi 1} u^n \mathrm{e}^{-\chi u}\, \partial u\right)^{-1}} \tag{7.36}$$

where u is a dummy variable. For first-order ractions, this simplifies to

$$\varphi = \frac{V_{\mathrm{p}}}{A_{\mathrm{p}}} \sqrt{\frac{k\left(T_{\mathrm{i}}\right)}{2\mathbb{D}_{\mathrm{i,\,A}}} \frac{\chi^2}{\mathrm{e}^{\chi} - 1 - \chi}} \tag{7.37}$$

In turn, for $\chi \to 0$, this simplifies to

$$\varphi = \frac{V_{\mathrm{p}}}{A_{\mathrm{p}}} \sqrt{\frac{k\left(T_{\mathrm{i}}\right)}{\mathbb{D}_{\mathrm{i,\,A}}}} \tag{7.38}$$

which is Aris' shape-generalized Thiele modulus for monomolecular first-order kinetics and insignificant intra particle temperature gradients.

In Figure 49 the effectiveness factor η is plotted against the Thiele modulus φ for first-order kinetics in an infinite slab and for varying values of χ. For $\chi = 0$ the curve discussed in Section 6.2.2.2 is obtained; for $\chi > 0$ (exothermic reactions) the effectiveness factor increases, and for $\chi < 0$ (endothermic reactions), η decreases. For high values of χ the effectiveness factor may even become larger than unity. In this case the temperature profiles inside the catalyst pellet are so pronounced that they can even compensate for the decreasing concentration inside the pellet. For very high values of χ, finally, even a region of multiplicity may be entered: for one value of the Thiele modulus, several values of the effectiveness factor can be obtained (in Fig. 49 for $\chi = 8$). This multiplicity results from the fact that

multiple solutions can be found if the mass and heat balances are solved simultaneously, as illustrated in Section 7.2 for mass and heat transfer and reaction in series.

To estimate the effectiveness factor from the Thiele modulus, one could again use the approximation (Eq. 6.116):

$$\eta = \frac{\tanh(\varphi)}{\varphi}$$

As shown in Figure 49 this approximation does not hold for high χ values ($\chi > 1$) and intermediate φ values. However, for mildly exothermic and all endothermic reactions the above approximation gives a fair estimate, usually within 10 % accuracy.

All the above formulas and conclusions also hold for systems in which Hatta numbers must be applied instead of Thiele moduli, as discussed above. For example, for monomolecular first-order reactions with mass and heat transfer with simultaneous reaction, the Hatta number becomes (see Eq. 7.37):

$$Ha = \frac{\mathbb{D}_A}{k_{l,A}} \sqrt{\frac{k(T_i)}{2\mathbb{D}_A} \frac{\chi^2}{e^{\chi} - 1 - \chi}} \tag{7.39}$$

It can be seen from the χ values in Table 1 that, in general, intrareaction-phase temperature gradients can be neglected, and the corrections for the Thiele moduli and Hatta numbers need not be applied.

1. Introduction

The reactor in which the chemical reaction takes place occupies a central position in the chemical process. Grouped around the reactor are the process steps involving physical treatment of the material streams, such as conveyance, heat transfer, and separation and mixing operations. The reactor provides the volume necessary for the reaction and holds the amount of catalyst required for the reaction. The energy required to overcome the activation threshold of each partial reaction is also supplied in the reactor, and the proper temperature and concentration are maintained.

The most important *reaction-related factors* for the design of a reactor are

1) The activation principle selected, together with the states of aggregation of the reactants and the resulting number and types of phases involved
2) The concentration and temperature dependence of the chemical reactions
3) The heat of the reactions taking place

The most important *activation principles* for a reaction mixture include

1) Activation by addition of heat
2) Catalytic activation
3) Activation by decomposition of an initiator
4) Electrochemical activation
5) Biochemical activation

Less important options for activation are visible or ultraviolet light and radioactive radiation.

With regard to *phase relationships* in the reaction space, a number of combinations are possible. The reactants and reaction products can be present, or be produced, in various states of aggregation. Furthermore, inert diluents or heat-transfer media can be present in different phases. Finally, the catalyst, which is generally in the solid or liquid phase, often has to be taken into consideration.

The (negative or positive) heat of the reactions taking place in a reactor influences the extent and nature of *provisions for heat transfer*. Exothermic or endothermic reactions frequently require supply or removal of large quantities of heat. Thermally neutral reactions involve considerably less technical sophistication.

The *concentration and temperature dependences* of a chemical reaction are described by the reaction rate. In practice most reaction systems are complex and include parallel, sequential, and equilibrium reactions. To obtain the highest possible yield of desired product under

these conditions, the temperature and pressure must be held within certain ranges, the temperature must be controlled along the reaction path, and a definite residence-time distribution in the reactor must be achieved. If, in addition, substances or energy have to be transferred from one phase to another, appropriate transport conditions have to be implemented. When catalysts are used, catalyst loss due to aging and poisoning must be considered. These factors impose a complex of requirements that must be kept in mind when designing a reactor.

Against the requirements established by the process, the designer must balance costs of fabrication, consumption of materials, and operational reliability. In practice, many possibilities are often available for realizing a chemical process, and in such cases the decision must depend on an assessment of the overall process as well as commercial constraints on the plant.

2. Basic Types of Reactors (→ Model Reactors and Their Design Equations)

A variety of reactor designs are used in industry, but all of them can be assigned to certain basic types or combinations of these. The basic types are as follows (see → Principles of Chemical Reaction Engineering, Chap. 4.2.):

1) Batch stirred-tank reactor
2) Continuous stirred-tank reactor
3) Tubular reactor

Given certain flow and thermal conditions, these types are also referred to as "ideal" reactors. With respect to *flow conditions* the ideal stirred-tank batch reactor is characterized by complete mixing on microscopic and macroscopic scales. In the ideal tubular reactor, plug flow is assumed, i. e., no mixing occurs in axial (flow) direction, but ideal mixing takes place in the ra-dial direction. Thus, as in the batch stirred-tank reactor, all particles experience a well-defined residence time. In contrast, the continuous stirred-tank reactor has a very broad residence-time distribution (→ Principles of Chemical Reaction Engineering, Chap. 4.2.1.). The ideal analysis is based on the assumption of a reaction system that is homogeneous as regards the phase. Thus transport resistance between phases does not occur.

The *thermally ideal operating states* are the isothermal and adiabatic states, i. e., either very intensive heat exchange with the surroundings or no exchange at all is assumed.

In practical operation, the ideal states are achieved only approximately. Examples of typical nonidealities include

1) The formation of real flow patterns, such as dead zones, short-circuit flows, and channeling
2) Transport processes in the individual phases, such as axial backmixing
3) The formation of concentration and temperature profiles as a result of transport resistances in and between phases
4) Segregation processes
5) Incomplete mixing of reactants

The essential advantages and disadvantages of the three basic reactor types are discussed in what follows.

Batch Stirred Tank (→ Stirred-Tank and Loop Reactors)

Principal Applications:

1) Liquid-phase reactions
2) Liquid – solid reactions

Advantages:

1) Quick production changeover possible; use for substances produced on a small scale
2) Process steps upstream or downstream of the reaction can also be performed in the reactor
3) Better process control than in continuous operation when solid or highly viscous phases form or are present
4) Well-defined residence time

Disadvantages :

1) Relatively high operating costs due to long downtimes and high manpower requirements
2) Quality differences between charges because reaction conditions are only partly reproducible
3) Limited temperature control capabilities, especially with highly endothermic or exothermic reactions

Continuous Stirred Tank
Principal Applications:

1) Liquid-phase reactions
2) Gas – liquid reactions
3) Gas – liquid reactions over suspended catalysts

Advantages:

1) Low operating costs, especially at high throughputs
2) Consistent product quality due to reproducible process control
3) Wide range of throughput

Disadvantages:

1) Final conversions lower than in other basic reactor types because of complete mixing (i.e., unreacted starting materials can get into the product stream)
2) High investment costs to implement continuous operation
3) Changeover to other products generally complex and time-consuming because of reaction-specific design

Tubular Reactor (→ Tubular Reactors)
Principal Applications:

1) Homogeneous gas-phase reactions
2) Liquid-phase reactions
3) Gas- and liquid-phase reactions over solid catalysts (→ Fixed-Bed Reactors)
4) Gas – liquid reactions

Advantages:

1) Favorable conditions for temperature control by heat supply or removal
2) No moving mechanical parts, hence especially suitable for high-pressure service

Disadvantages:

1) Very high degree of specialization, often with complicated design and high investment costs
2) Relatively large pressure drops

Reactors are interconnected to make up for the drawbacks of a single reactor, especially to adapt reaction conditions during scale-up capacity, as well as to optimize conversion and yield. Partial reactors can be combined in a single apparatus or connected in a system of reactors; these partial reactors may differ in shape and size.

Types of interconnections are series, parallel, and recycle.

Series Connection:

1) Multibed reactors
2) Tower reactors, reaction columns
3) Cascades of stirred tanks (→ Stirred-Tank and Loop Reactors)
4) Multiple-hearth reactors (→ Metallurgical Furnaces, Chap. 2.)
5) Different reactor types connected in series (e.g., stirred tank and tubular reactor)

Parallel Connection: Multitubular reactors
Recycle Connection: Loop reactors (→ Stirred-Tank and Loop Reactors)

Complicated reactor designs result, especially when different reactor types are combined in a single apparatus. At the same time, such a combination offers maximum adaptability to the requirements of a given reaction process. The designer must, of course, examine every case individually to ensure that the results justify the very high development and investment costs for such special reactors. The following survey of real reactors includes these special types of reactor designs only when their utility extends beyond a single case.

3. Survey of Real Reactors and Their Uses

The phase relationships in the reaction space are crucial in the design of reactors for *catalytic, thermal, and polymerization processes* and accordingly form the top-level classification feature for such reactors. Since many different combinations of phases are possible, the survey is based only on the state of the reactants at the inlet to the reactor or the beginning of the reaction and the phase of the reaction site (catalyst phase, liquid phase with dissolved reactant). Reaction products that form additional phases and inert substances of all types (except for solvents, as just noted) are ignored.

Reactors used in *electrothermal, electrochemical, biochemical, photochemical,* and *radiochemical* processes are treated separately. Reactor types for which no industrial application is currently known are not listed.

3.1. Reactors for Gas-Phase Reactions

Homogeneous gas-phase reactions utilized in industry are generally characterized by large positive or negative enthalpies of reaction and high reaction temperatures. To obtain the desired product spectrum, residence times must usually be very short. The high reaction temperature can be maintained or the requisite heat supplied by burning part of the feed.

Tables 1 and 2 and Figures 1 and 2 summarize the reactors used for such reactions as well as their applications.

3.2. Reactors for Liquid-Phase Reactions

In general, liquid-phase reactions are exothermic. In the case of multiphase systems, intensive mass and heat transfer must be provided for; this is possible only in reactors with compulsory mixing, such as stirred tanks. Along with a num-

Table 1. Reactors for exothermic gas-phase reactions

Reactor type	Features	Examples of applications
Burner	for high reaction rates	combustion of H_2S to SO_2 (Claus vessel)
	very high reaction temperatures	carbon black production (furnace, gas, thermal carbon black processes)
	explosion limits must be taken into consideration	chlorine – hydrogen reaction
		chlorination of methane
		nitration of propane
Tubular reactor	well-defined residence time (tubes up to 1000 m long)	chlorination
		of methane
	intermediate injection possible	of propene to allyl chloride
	pressure drops	of butadiene to dichlorobutane
	good temperature control capability	chlorolysis of chlorinated hydrocarbons
Reactor with recycle	suitable for low reaction rates	chlorination of methane
	good mixing	
	cooling inside or outside reactor	
Fluidized-bed reactor	nearly isothermal conditions because heat transport is very efficient	chlorination
		of methane
	intensive mixing	of 1,2-dichloroethane to tri- and perchloroethylene
		chlorolysis of chlorinated hydrocarbons

Table 2. Reactors for endothermic gas-phase reactions

Reactor type	Features	Examples of applications
Burner	very high reaction temperatures attainable by partial combustion of reactants	Sachsse – Bartholomé process for acetylene production
	short residence times	high-pressure gasification for synthesis gas production (Texaco, Shell)
Reformer	high reaction temperatures attainable mainly by radiation	steam cracking of naphtha and other hydrocarbons to ethylene
	well-defined residence times	vinyl chloride production by cleavage of dichloroethane
		pyrolysis
		of acetic acid to ketene
		of 2-methyl-2-pentene
		to isoprene (in presence of HBr)
		of chlorodifluoromethane
		to tetrafluoroethylene
Fluidized-bed reactor	heat supplied along with solids	Lurgi Sandcracker
Moving-bed reactor	heat supplied along with solids	Langer – Mond process for production of ultrapure nickel
	continuous removal of solid products	
Reactor with fixed bed of inerts	fixed bed ensures heat storage and intensive mixing	Kureha process for acetylene and ethylene production
		production of CS_2 from CH_4 and sulfur vapor
Regenerative furnaces	battery operation	gas generation from heavy crudes
	no dilution by heat-transfer medium	

ber of other reaction types, nearly all industrially important polymerization reactions take place in the liquid phase. For the sake of completeness,a few important exceptions among polymerization reactions are included in this section, even though they do not fall under liquid-phase reactions according to the classification principle stated above. These are, in particular, "gas-phase polymerization" reactions, some of which take place over solid complex catalysts of the Ziegler – Natta type (high-density polyethylene, linear low-density polyethylene, and polypropylene).

The essential feature of polymerization reactions is that, in contrast to other liquid-phase reactions, the viscosity increases rapidly during the course of reaction and causes difficulties in heat and mass transport. In industry, this problem is countered by (1) the use of special stirring and kneading devices; (2) running the process in several stages; (3) raising the temperature as the conversion increases; and (4) carrying out polymerization in thin films.

Table 3. Reactors for liquid-phase reactions (one or more phases present)

Reactor type	Features	Examples of applications
Tubular reactor	well-defined residence time good temperature control capabilities	polymerization reactions bulk polymerization to LDPE ∗ polycondensation to PA 66 ∗ (2nd stage) hydrolysis reactions of ethylene oxide and propylene oxide to glycols of chlorobenzene to phenol and chlorotoluene to cresol of allyl chloride production of ethyl acetate from acetaldehyde production of isopropanolamine dehydrochlorination of 1,1,2-trichloroethane to vinylidene chloride
Reformer	high reaction temperature well-defined residence time	visbreaking delayed coking pyrolytic dehydrochlorination of tetrachloroethane to trichloroethylene high-pressure gasification of heavy crudes
Multitubular reactor	large heat-transfer area multistage design with stirring elements between stages is possible	bulk polymerization to PS ∗, HIPS ∗, and SAN ∗
Sulzer mixer – reactor (plug-flow configuration)	mixing elements consist of tubes carrying heat-transfer medium large heat-transfer area suitable for processes in which viscosity increases intensive radial mixing with little axial backmixing very narrow residence-time distribution	bulk polymerization to PS ∗ and polyacrylates temperature-controlled starch conversion
Reactor with external recirculation	good mixing and heat-removal conditions no moving parts suitable for low reaction rates heat exchanger can be placed outside reactor	cleavage of cumene hydroperoxide to phenol and acetone (2nd stage of Hock process) Beckmann rearrangement of cyclohexanone oxime to caprolactam production of hydroxylamine sulfate (Raschig process) production of phosphoric acid (wet process) saponification of allyl chloride bulk polymerization to PS ∗, HIPS ∗, SAN ∗, and PMMA ∗
Reactor with internal recirculation	very intensive mixing	production of melamine from molten urea (high-pressure process) production of aromatic nitro compounds production of adipic acid from cyclohexanol and nitric acid Bulk polymerization to PS ∗, HIPS ∗, and SAN ∗
Loop reactor	for slurry polymerization suspension is circulated at high velocity to prevent buildup	polymerization reactions slurry polymerization to PP ∗ production of HDPE ∗ and LLDPE ∗
Powder-bed reactor	liquid monomers supported on already polymerized granules for high conversion evaporating and condensing monomer acts as heat-transfer agent (boiling, cooling) vertical and horizontal designs	polymerization reactions polymerization to HDPE ∗ and PP ∗ block copolymerization to PE – PP ∗ precipitation polymerization to PAN ∗, IIR ∗, PE ∗, PP ∗

Table 3. Continued

Reactor type	Features	Examples of applications
Stirred tank, batch or semicontinuous	limited heat-transport capability mechanical stirring means suitable for slow reactions	polymerization reactions bulk polymerization to PS ∗, PMMA ∗, HIPS ∗, ABS ∗ (1st stage of each process) polycondensation to PA 66 ∗ solution polymerization to PVAC ∗, PAN ∗, PE ∗, PP ∗, EPM ∗, EPDM ∗, SB ∗, SB – S ∗, EO – PO ∗ polycondensation to UF ∗, MF ∗, PF ∗ resins precipitation polymerization to PVC ∗, PAN ∗, PE ∗, PP ∗, EPM ∗, EPDM ∗ suspension polymerization to PVC ∗, EPS ∗, PMMA ∗, PVAC ∗, and ion-exchange resins based on PS ∗, HIPS ∗, ABS ∗ (2nd stage) emulsion polymerization to numerous polymer dispersions production of aromatic nitro compounds sulfonation of benzene esterification of PA ∗ and alcohol to diphthalates many other syntheses of dyes and pharmaceuticals
Stirred tank, continuous	suitable for fast reactions with large negative or positive heat of reaction approximately complete mixing conversion generally not complete mechanical stirring means	polymerization reactions bulk and solution polymerization to PS ∗, PMMA ∗, HIPS ∗, and ABS ∗ (1st stage in each case); copolymers with nonazeotropic monomer ratios precipitation polymerization to PAN ∗, IIR ∗, PE ∗, PP ∗ emulsion polymerization to PVC ∗ and SAN ∗ esterification of acrylic acid with alcohol of acetic acid with ethanol dehydration of 1,4-butanediol to tetrahydrofuran of ethanol to diethyl ether saponification of benzyl chloride of fatty acids dehydrochlorination of 3,4-dichloro-1-butene to chloroprene of 1,1,2-trichloroethane to vinylidene chloride cyclization of glycols to 1,4-dioxane nitration of aliphatic hydrocarbons alkylation of isobutane with *n*-butenes production of melamine from molten urea (Montecatini) oxidation of cyclohexanone/ol with HNO_3 to adipic acid of mono- to dicarboxylic acids of allyl alcohol with H_2O_2 to glycerol
Cascade of stirred tanks	suitable for slow reactions adaptable to needed reaction conditions stage by stage residence-time distribution close to that of tubular reactor	polymerization reactions transesterification of DMT ∗ to DGT ∗ polycondensation to PETP ∗ and PBT ∗ solution polymerization to BR ∗, IR ∗, UP ∗, UF ∗, MF ∗, PF ∗ resins solution or precipitation polymerization to PE ∗, PP ∗, EPM ∗, EPDM ∗ emulsion polymerization to SBR ∗, CR ∗, NBR ∗ production of hydroxylamine sulfate (Raschig process) production of cyclohexanone oxime from cyclohexanol and hydroxylammonium sulfate nitration of aromatic hydrocarbons decomposition of ammonium carbamate to urea production of plasticizers from phthalic anhydride and alcohol production of MDA ∗ in conjunction with downstream tubular reactor production of methacrylamide from acetocyanohydrin production of MDI ∗ from MDA ∗ and TDI ∗ from TDA ∗

Table 3. (Continued)

Reactor type	Features	Examples of applications
Reaction column	reaction and separation in a single apparatus equilibrium can be modified by removing one or more components from reaction space	aldol condensation of *n*-butyraldehyde to 2-ethylhexenal saponification of chloropropanol with milk of lime of fatty acids esterification of acetic acid with butanol of phthalic anhydride with alcohols decomposition of amalgam of ammonium carbamate to urea and water
Multichamber tank	virtually identical to cascade of stirred tanks requires little space chamber-by-chamber feed injection possible	polymerization to LDPE ∗ (ICI) alkylation of isoparaffins with olefins (Kellogg)
Tower reactor	for continuous processes section-by-section temperature control possible little backmixing at high viscosity also in cascade or with upstream stirred tank	bulk and solution polymerization of PS ∗, HIPS ∗, ABS ∗, SAN ∗, PA 6 ∗
Ring-and-disk reactor	narrow residence-time distribution	final stage in production of PETP ∗ and PBT ∗
Extruder	for highly viscous media	polymerization reactions production of POM ∗ from trioxane final stage in production of PA 66 ∗
Fluidized-bed reactor	very good heat- and mass-transport conditions	polymerization to HDPE ∗, LLDPE ∗, PP ∗ fluid coking of heavy residual oils (Exxon) melamine production from molten urea
Mixing head with injection mold	special design for bringing several liquid reactants together	production of PUR ∗
Belt reactor with mixing head	for fabrication of sheets and films	production of PIB ∗, PMMA ∗, PUR ∗, PVAL ∗
Spinning jet (with coagulating bath)	for production of strands	viscose spinning
Spray reactor	direct heating in hot stream of gas	thermal H_2SO_4 cleavage production of MgO from $MgCl_2$ (spray calcination)
Falling-film reactor	gentle temperature control due to large heat-transfer area	sulfation of fatty alcohols diazotization of aromatic amines diazo coupling

∗ The following abbreviations are used: ABS = acrylonitrile – butadiene – styrene copolymer; BR = butadiene rubber; CR = chloroprene rubber; DGT = diglycyl terephthalate; DMT = dimethyl terephthalate; EO – PO = ethylene oxide –propylene oxide block copolymer; EPDM = ethylene – (propene – diene) copolymer; EPM = ethylene – propene copolymer; EPS = expandable polystyrene; HDPE = high-density polyethylene; HIPS = high-impact polystyrene; IIR = isobutylene – isoprene rubber (butyl rubber); IR = isoprene rubber (synthetic); LDPE = low-density polyethylene; LLDPE = linear low-density polyethylene; MA = maleic anhydride; MDA = 4,4′-diaminodiphenyl methane; MDI = methylene diphenylene isocyanate; MF = melamine – formaldehyde; NBR = butadiene – acrylonitrile copolymer (nitrile rubber); PA = polyamide; PAN = polyacrylonitrile; PBT = poly(butylene terephthalate); PE = polyethylene; PE – PP = polyethylene – polypropylene copolymer; PETP = poly(ethylene terephthalate); PF = phenol – formaldehyde; PIB = polyisobutylene; PMMA = poly(methyl methacrylate); PO = poly(propylene oxide); POM = polyoxymethylene; PP = polypropylene; PS = polystyrene; PUR = polyurethane; PVAC = poly(vinyl acetate); PVAL = poly(vinyl alcohol); PVC = poly(vinyl chloride); SAN = styrene – acrylonitrile copolymer; SBR = styrene – butadiene rubber; SB = styrene –butadiene block copolymer; SB – S = styrene – butadiene – styrene block copolymer; TDA = toluene diamine; TDI = toluene diisocyanate; UF = urea – formaldehyde; UP = unsaturated polyester.

Table 3 and Figures 3) and 4 summarize the types of reactors used in industry for liquid-phase reactions. Figure 4 shows special reactor designs for polymerization reactions.

3.3. Reactors for Gas – Liquid Reactions

Gas – liquid reactions include many industrially important processes, such as oxidation, alkylation, chlorination, and flue-gas scrubbing. The prerequisite for an efficient reaction is rapid mass transport between gas and liquid. Important criteria for assessment include

1) The interfacial area
2) The mass or volume ratio of gas to liquid
3) The energy required to mix the phases

Other important factors are temperature control, heat removal, and residence time (especially that of the liquid phase).

Reactor design is dictated largely by the way in which the interface is generated. The following methods are possible:

1) Reactors with continuous liquid-phase and fixed gas distribution devices [bubble columns (→ Bubble Columns), packed and tray reactors (→ Reaction Columns)]
2) Reactors with mechanical gas dispersion (sparged stirred tanks)
3) Reactors with continuous gas phase and liquid dispersing devices (spray reactors, liquid-ring pumps)
4) Thin-film reactors (→ Thin-Film Reactors)

Figure 5 illustrates reactor types for gas – liquid reactions. Important applications are listed in Table 4.

Table 4. Reactors for gas – liquid reactions

Reactor type	Features	Examples of applications
Tubular reactor (with injection)	large transfer areas can be provided temperature can be controlled by indirect transfer well-defined residence time little backmixing	production of adiponitrile from adipic acid and ammonia production of nitroaniline by amidation of chloronitrobenzene oxidation of ethylene to acetaldehyde (2nd stage)
Bubble column	can be equipped with internal draft tube or external recirculation simple design practically isothermal conditions can be achieved by evaporation of a liquid component limited temperature and pressure ranges suitable for continuous and semicontinuous operation high backmixing in liquid phase	oxidation of ethylene to acetaldehyde of toluene to benzoic acid of cyclohexane to cyclohexanone/ol of acetaldehyde to acetic acid and acetic anhydride of cumene to cumene hydroperoxide of *p*-xylene to dimethyl terephthalate (1st stage) of butane to acetic acid of butene to ketones of propane to acetone of copper chlorides to copper oxychlorides alkylation of benzene with ethylene and propene epoxidation of propene with organic hydroperoxides (Halcon) hydroformylation of propene (oxo synthesis) chlorination of benzene to chlorobenzene of ethylene to 1,2-dichloroethane of alkalies to hypochlorites of 1,2-dichloroethane or vinyl chloride to 1,1,2-trichloroethane production of acrylic acid or acrylates from acetylene, CO, and water or alcohol decarboxylation of benzoic acid to phenol production of vinyl ether from acetylene and alcohol carboxylation of methanol to acetic acid production of methylpyridine from ethylene and ammonia hydrolysis of trichloroethylene to monochloroacetic acid hydration of acetylene to acetaldehyde production of propionic acid from ethylene, CO, and water (Reppe process)
Reactor with external recirculation	heat exchangers in external loop mixing elements can be included suitable for continuous and batch processes	alkylation of *o*-toluidine with ethylene of phenol with isobutene air oxidation of liquid hydrocarbons
Liquid-ring pump	combines compression, absorption, and reaction	production of acetic anhydride from acetic acid and ketene

Table 4. Continued

Sparged stirred tank	continuous and semicontinuous operation possible stirrer shaft must be sealed much backmixing in both phases external liquid recirculation can be added	oxidation of *p*-xylene to terephthalic acid (Amoco process) of ethylene to acetaldehyde of propene to acetic acid of benzoic acid to phenol of cyclohexane to cyclohexanone/ol of toluene to benzaldehyde of butene to methyl ethyl ketone of cyclohexanol to adipic acid of acetaldehyde to acetic anhydride alkylation of benzene with ethylene chlorination of aromatics hydrogenation of natural fats to fatty acids or their esters acetylation of carboxylic acids to vinyl ethers production of pure SO_2 from liquid sulfur and SO_3
Cascade of stirred tanks	narrower residence-time distribution than single tank	epoxidation of propene with organic hydroperoxides (Halcon process) hydrolysis of fats to fatty acids and glycerol production of phthalic acid (Progil)
Reaction column	tray or packed column design combination of reaction and separation permits control of equilibrium cocurrent or countercurrent operation	oxidation of ethylbenzene, cumene, isobutane to the hydroperoxides (1st stage of Halcon process) production of chloropropanols from propene, chlorine, and water absorption of nitrogen oxides in nitric acid production of ammonia and CO_2 in soda production of gases in scrubbers (with amines) chlorination of ethylene to 1,2-dichloroethane of acetylene to tetrachloroethane of trichloroethylene to perchloroethane hydrochlorination of ethylene to chloroethane precipitation of $NaHCO_3$ in soda production production of sulfonic acids (benzene-, chlorosulfonic acids) high-temperature debromination of salt brines production of alkyl and dialkyl sulfates production of phthalimide from phthalic anhydride and NH_3 production of ammonium nitrate from HNO_3 and NH_3
Spray reactor (jet scrubber)	suitable for high gas throughputs and high gas-side solids transport resistance very large interfacial areas	gas treatment and off-gas scrubbing production of acetic anhydride from acetic acid and ketene production of H_3PO_4 (Knapsack process) acid refining of lubricants hydrolysis of dichlorodimethylsilane production of potassium hyperoxide by contacting of molten potassium with air
Falling-film reactor	gentle temperature control due to large heat-transfer area	Sulfonation of dodecylbenzene, fatty alcohols, and olefins
Rotary kiln	for reaction of molten solids with gases	oxidation of sodium to sodium peroxide (two-stage process) of molten sulfur to SO_2

3.4. Reactors for Solid-Catalyzed Reactions

Heterogeneous catalytic processes play a major role in chemical technology, because many key products and intermediates can be manufactured in this way. Fluid reactants react in the presence of a solid catalyst, the mechanism as a whole consisting of the reaction proper and a series of upstream and downstream transport steps.

3.4.1. Reactors for Heterogeneous Gas Catalysis

Reactors with a fixed catalyst bed are distinguished from those with moving catalyst.

Fixed-Bed Reactors (→ Fixed-Bed Reactors). The characteristic features of a reactor with fixed catalyst are the pressure drop of the flowing gas in the catalyst bed and the danger of unstable operation points, especially with strongly exothermic reactions, when flow through the catalyst bed becomes nonuniform. Fixed-bed reactors must be shut down after a certain time onstream to regenerate or replace the catalyst.

Fixed-bed reactors can be classified by the type of temperature control:

1) Reactors with no special temperature control features (adiabatic operation)
2) Reactor systems with stagewise temperature control (chiefly for equilibrium reactions)
3) Reactors with continuous heat exchange along the flow path (polytropic operation)

Fixed-bed reactors *without equipment for temperature control* are marked by a particularly simple construction and low flow resistance, which makes them suitable for high gas throughputs. A summary of these reactors appears in Table 5 and Figure 6.

Reactor systems with *stagewise temperature control* are used primarily for equilibrium reactions. Such a reactor consists of simple adiabatic reactor elements connected in series and takes the form of several units or a system housed in a common reactor shell. Temperature control is accomplished by heat transfer between reactor stages or by the injection of tempered gas or vapor streams at points along the flow path. Table 6 and Figure 7 present reactor systems of this type along with applications.

If the reaction process imposes special requirements on temperature control, heat-transfer surfaces must be located throughout the reactor volume. The best-known design for such a reactor is the *multitubular reactor*, which is frequently used in the chemical industry. The drawbacks relative to other fixed-bed reactors include the much more complicated design and the limitation on throughput due to the smaller cross-sectional area available for flow.

Temperature control is achieved by the use of gaseous and liquid heat-transfer media. One highly effective approach is the use of boiling liquids (e.g., pressurized-water and evaporatively cooled reactors). A special case is the autothermal process regime, in which the reaction mixture itself is used as a temperature control medium before it flows through the catalyst bed. Fixed-bed reactors with *continuous heat exchange* are described in Table 7 and Figure 8, along with applications.

Moving-Bed and Fluidized-Bed Reactors (→ Fluidized-Bed Reactors). In moving-bed reactors, transport of the catalyst is influenced by gravity and the drag force exerted by the flowing reaction fluid on the catalyst particles. The regime in the reactor can vary widely, depending on the ratio of these forces. The fol-lowing features must be taken into consideration when using reactors of this type:

1) The possibility of continuous catalyst regeneration
2) Increased mechanical loads on the catalyst and reactor materials
3) The favorable conditions for heat and mass transport, resulting from rapid movement of solids and small catalyst grain size

Table 8 and Figure 9 list reactor types and applications.

3.4.2. Reactors for Liquid-Phase and Gas – Liquid Reactions over Solid Catalysts

Fixed-bed reactors (trickle-flow reactors and packed bubble columns) are used for liquid-phase reactions, as well as gas – liquid reactions over solid catalysts. The presence of a liquid

Table 5. Fixed-bed catalytic reactors for gas-phase reactions with no special provisions for temperature control

Reactor type	Features	Examples of applications
Simple fixed-bed reactor (axial flow)	very simple design not suitable for reactions with large positive or negative heat of reaction and high temperature sensitivity	reforming (Platforming, Rheniforming, etc.) hydrotreating CO converting amination of methanol to methylamines desulfurization and methanation in synthesis-gas path upstream of primary reformer hydrogenation of nitrobenzene to aniline (Allied, Bayer) production of vinyl propionates from acetylene and propionic acid isomerization of *n*-alkanes dehydrogenation of ethylbenzene to styrene disproportionation of toluene to benzene and xylene
Fixed-bed reactor with combustion zone	direct heating by combustion of part of hydrocarbon feed	methane cleavage in secondary reformer
Radial-flow reactor	much lower pressure drop than axial-flow reactor multistage configuration possible enhanced backmixing due to small thickness of bed uniformity of flow requires exact sizing of distributing and collecting ducts	ammonia synthesis (Topsoe, Kellogg) dehydrogenation of ethylbenzene to styrene (Dow) reforming
Shallow-bed reactor	used for high reaction rates and unstable products very short residence time catalyst can also be in gauze form suitable for autothermal operation	oxidation of ammonia to NO_x oxidative dehydrogenation of methanol to formaldehyde production of hydrocyanic acid from ammonia, methane, and air (Andrussow process)
Regenerative furnace	suitable when catalyst ages rapidly and can be regenerated by burning off reaction heat can be supplied by catalyst regeneration battery operation	dehydrogenation of butane to butadiene (Houdry process) SO_2 reduction with methane (Andrussow process)

Table 6. Fixed-bed catalytic reactors for gas-phase reactions with stagewise temperature control

Reactor type	Features	Examples of applications
Cascade of fixed-bed reactors	large pressure and temperature differences are possible	reforming of heavy gasoline hydrocracking conversion of H_2S and SO_2 to elemental sulfur (Claus process) isomerization of five-to-six-ring naphthenes
Multibed reactor with cold-gas injection	used for exothermic equilibrium reactions injection of reaction mixture leads to lower conversion and thus increased number of stages injection of water lowers concentration at constant conversion adaptation of bed depth to progress of reaction	ammonia synthesis methanol synthesis hydrocracking hydrogenation of benzene desulfurization of vacuum gas oil
Multibed reactor with interstage cooling	used for exothermic equilibrium reactions internal or external heat exchangers no dilution effects adaptation of bed depth to progress of reaction	ammonia synthesis (ÖSW, Fauser, Montecatini) SO_2 oxidation (with interstage adsorption) hydrodealkylation of alkyl aromatics
Multibed reactor with heat supply	used for endothermic equilibrium reactions interstage heating or interstage injection of superheated steam	dehydrogenation of ethylbenzene to styrene (Dow)

Table 7. Fixed-bed catalytic reactors for gas-phase reactions with continuous temperature control

Reactor type	Features	Examples of applications
Multitubular reactor	temperature control with liquid, gaseous, or boiling heat-transfer agent in shell-side space relatively expensive design high cost and long downtime for catalyst replacement internals in shell-side space to improve heat transfer distribution devices needed for stream of reaction gas in large reactors relatively large pressure drop autothermal processing possible	oxidation of ethylene to ethylene oxide of *o*-xylene or naphthalene to phthalic anhydride of propene to acrolein or acrylic acid of acrolein to acrylic acid of methanol to formaldehyde (Formox process) of naphthalene to 1,4-naphthoquinone of ethanol to acetaldehyde alkylation of benzene with ethylene or propene to ethylbenzene, diethylbenzene, or cumene (Mobil, Badger processes) hydrogenation of CO to methanol (Lurgi low-pressure process) ammonia synthesis (TVA, NEC processes) of phenol to cyclohexanone/ol of natural fats to fatty acids dehydrogenation of ethylbenzene to styrene of diethylbenzene to divinylbenzene of cyclohexanol to cyclohexanone of 2-butanol to methyl ethyl ketone of ethanol to acetaldehyde hydration of propene to isopropanol dehydration of phenylmethylcarbinol to styrene of acetic acid to acetic anhydride of ethanol to diethyl ether oxychlorination of ethylene to ethylene dichloride (Stauffer process) production of vinyl acetate from acetic acid and ethylene or acetylene production of methyl *tert*-butyl ether from methanol and isobutene (1st stage) hydrochlorination of acetylene to vinyl chloride of methanol or ethanol to chloromethane or chloroethane
Tubular furnace	direct heating of catalyst tubes for endothermic reactions and high reaction temperatures	primary reformer
Fixed-bed reactor with heating or cooling elements	advantageous when only the heating or cooling system has to be designed for special pressure conditions classical examples are Fischer–Tropsch reactor and butadiene reactor of four-stage process	methanol synthesis (Linde isothermal reactor)

phase, however, leads to much greater drag and friction forces on the catalyst. If the reaction involves both gas and liquid phases, maintenance of uniform flow conditions through the catalyst bed and intensive mixing of the phases can be difficult. The crucial factor for the efficiency of catalytic processes is the wetting of the catalyst by the liquid. Since reactors of this type are usually operated adiabatically, local overheating is a danger, especially with exothermic reactions. Fixed-bed reactors are well suited to high-pressure processes by virtue of their simple design.

A second important group includes *suspension reactors*, in which very fine catalyst particles are distributed throughout the volume of the liquid (stirred tanks and bubble columns

with suspended catalyst). Because transport resistances are reduced, these reactors offer a close approach to isothermal operating conditions and a favorable utilization of the catalyst volume.

Sophisticated techniques are required to separate the finely divided catalyst from the liquid. Equipment for this purpose can be installed inside or outside the reactor. At the same time, this arrangement permits continuous catalyst replacement. All suspension reactors have the disadvantage of increased backmixing, especially of the liquid phase, which affects product distribution.

The *fluidized-bed reactor* differs from the suspension reactor in the use of coarser catalyst particles and the formation of a well-defined agitated catalyst bed below the liquid level.

Industrially important reactors for liquid-phase and gas – liquid reactions over solid catalysts are listed, together with their applications, in Tables 9 and 10 and Figures 10 and 11.

Table 8. Moving-bed catalytic reactors for gas-phase reactions

Reactor type	Features	Examples of applications
Moving-bed reactor	gravity transport of catalyst	cracking (TCC, Houdry flow process)
	reaction conditions largely similar to those in fixed-bed reactor	dehydrogenation of butane
	advantageous when catalyst can be regenerated by burning off residues	
Fluidized-bed reactor	catalyst agitated by gravity and resistance force of gas flow	cracking (Kellogg, FFC, Flexicracking)
	almost isothermal conditions can be achieved in fluidized bed	hydrocracking
	pressure drop independent of gas throughput over a wide range	reforming
	form of fluidized bed can be varied as a function of geometric and hydraulic conditions	ammoxidation
	strong backmixing internals to improve mass transport and heat transfer are common	of propene to acrylonitrile (Sohio process)
	catalysts must have high abrasion resistance	of *o*-xylene to *o*-phthalodinitrile
		production of adiponitrile from adipic acid and ammonia
		oxychlorination of ethylene to 1,2-dichloroethane (Goodrich)
		production of melamine from urea (BASF)
		hydrogenation
		of nitrobenzene to aniline (BASF, Cyanamid)
		of ethylene
		oxidation
		of *o*-xylene or naphthalene to phthalic anhyride
		of butane to MA∗ (Du Pont)
		of SO_2 to SO_3
		of ethylene to ethylene oxide
		of NH_3 to NO
		of HCl to chlorine
		dehyrogenation
		of isopropanol
		of *n*-butane to *n*-butene
		production of chloromethylsilanes from chloromethane (catalytic gas – solid reaction)
		production of vinyl chloride (Cloe process)
		chlorination of methane and ethylene
		production of butadiene from ethanol
		isomerization of *n*-butane
		production of isoprene
		postchlorination of PVC∗
		combustion
Entrained-flow reactor	uses very fine-grained catalyst	Fischer – Tropsch process (Synthol process)
	whole quantity of catalyst circulates continuously between reaction section and tempering or regeneration unit	

∗ For abbreviations, see footnote to Table 3

3.5. Reactors for Noncatalytic Reactions Involving Solids

A variety of specialized reactors are available for noncatalytic reactions involving solids. The discussion that follows deals only with the industrially important types.

3.5.1. Reactors for Noncatalytic Gas – Solid Reactions

In general, noncatalytic gas – solid reactions are characterized by low overall reaction rates and

Table 9. Fixed-bed catalytic reactors for liquid-phase and gas – liquid reactions

Reactor type	Features	Examples of applications
Trickle-flow reactor	can operate in cocurrent or countercurrent	desulfurization and refining of petroleum products
	temperature control by intermediate injection or recirculation	hydrocracking
	danger of uneven liquid distribution and incomplete wetting of catalyst	production of butynediol from acetylene and formaldehyde
	narrow residence-time distribution	direct hydration of propene to 2-propanol (Texaco)
		hydrogenation
		of organic intermediates (butynediol, adiponitrile, ethylhexenal)
		of aldehydes, esters, and carboxylic acids to alcohols
		of natural fats to fatty acids
		of residues (low-temperature hydrogenation of tars)
		posthydrogenation
Packed bubble column	danger of flooding limit throughput capacity	amination of alcohols
	catalyst subject to greater mechanical stress (retention necessary)	cobaltizer and decobaltizer in oxo synthesis
	high liquid proportion promotes heat removal	disproportionation of toluene to benzene and xylene
	large amount of backmixing in liquid phase	

Table 10. Suspended-bed and fluidized-bed reactors for liquid-phase and gas – liquid reactions over solid catalysts

Reactor type	Features	Examples of applications
Bubble column with suspended catalyst	simple design	hydrogenation
	small pressure drop	of CO (Fischer – Tropsch synthesis)
	danger of undesired liquid-phase reactions	of tars and coals (bottom phase)
	inhomogeneous catalyst distribution must be prevented	of benzene to cyclohexane
	suitable if product drops out as solid	hydrodesulfurization
Reactor with external recirculation	heat-exchange and mixing devices in external loop	hydrogenation of organic intermediates (nitrobenzenes, nitriles, nitronaphthalenes, etc.)
	for continuous and batch operation	
	catalyst separation outside reactor	
Sparged stirred tank with suspended catalyst	can also be operated in semicontinuous and batch modes	hydrogenation of organic intermediates (nitro compounds, aromatics, butynediol)
	ensures intensive mixing of all phases	fat hydrogenation
	increased cost for sealing and maintaining stirrer drive	catalytic refining
Cascade of sparged stirred tanks with suspended catalyst	higher final conversions than in single stirred tank	hydrogenation of NO to hydroxylamine
	suitable for slow reaction rates	continuous hydrogenation of fats
	adaptable to intermediate injection and other interconnections	hydrolysis of fats to fatty acids and glycerol production of toluenediamine from dinitrotoluene
Fluidized-bed reactor	small pressure drop catalyst must have very high mechanical strength	hydrocracking and desulfurization of heavy petroleum fractions and still residues (H-Oil process; three-phase fluidized bed)

high process temperatures; in addition, the structure and geometry of the solid can change during the reaction.

Reactors for this service can essentially be grouped into those for semicontinuous operation, that is, *with no solids transport* (vertical shaft kilns and rotary drums), and those for continuous operation, that is, with *continuous solids transport*. The second type, in turn, can be divided into

1) Reactors with gravity transport of solids
2) Reactors with mechanical transport of solids
3) Reactors with pneumatic transport of solids

These three groups differ widely with respect to residence time, conditions of mass and heat transport between gas and solid phases, and heat-input capabilities. The first group includes *moving-bed reactors*. Since the gas has to flow through the bed of solids, mass and heat transport between the phases is relatively good. Temperature control can be effected by simultaneously carrying out exothermic and endothermic reactions in the same reactor.

Reactors with mechanical transport of solids include *rotary kilns* and *multiple-hearth furnaces* (→ Metallurgical Furnaces, Chap. 1., → Metallurgical Furnaces, Chap. 2.). Transport of gas and solid phases through the reactor largely occurs separately. Intensive heat and mass transfer occurs only at the surface of the bed of solids. Complete involvement of the solid phase in the reaction process depends on continuous, intensive mixing of the solids. Heat is often supplied directly by burners. More than one unit can be in operation in a single apparatus (e.g., drying, heating, cooling, and various reaction steps).

Figure 10. Fixed-bed catalytic reactors for liquid-phase and gas – liquid reactions
A) Trickle-flow reactor (countercurrent); B) Trickle-flow reactor (cocurrent); C) Packed bubble column
a) Liquid reactants; b) Gaseous reactants; c) Liquid product; d) Off-gas; e) Catalyst; f) Rupture disk

Solids transport by the gas stream is possible only with small particle sizes and the narrowest possible grain-size distribution. This group includes *fluidized-bed* and *entrained-flow reactors, dust roasters*, and *suspension furnaces*. Because of the favorable conditions for heat and mass transport, these reactors offer shorter residence times and thus higher throughputs than other types. The installation of heat-transfer surfaces, supplementary solid heat-transfer media, and direct heating is possible.

Industrially important reactor types for noncatalytic gas – solid reactions are listed in Table 11 and Figure 12 along with applications.
.

3.5.2. Reactors for Noncatalytic Liquid – Solid Reactions

Reactors used for noncatalytic liquid – solid reactions must be designed for the transport and mixing of phases, sometimes at high solids contents. Batch and semicontinuous designs are therefore dominant. Table 12 and Figure 13 present a survey of important reactor types for noncatalytic liquid – solid reactions and sample applications.

3.5.3. Reactors for Noncatalytic Solid-Phase Reactions

Reactors used for noncatalytic solid-phase reactions are similar to those used for noncatalytic gas – solid reactions. Long residence times and high reaction temperatures are necessary, especially for reactions between different solids, because of the low transport rates therein. Heat can be supplied by indirect or direct heating or by burning solid fuels.

Inert gases are employed for heat transport and agitation of the solids. Important applications are listed in Table 13.

3.6. Electrothermal Reactors

A variety of electrical heating schemes are used for some important noncatalytic reactions between gases and solids when very high reaction temperatures and large quantities of heat are required. In the simplest case, heating elements

Table 11. Reactors for noncatalytic gas – solid reactions

Reactor type	Features	Examples of applications
Shaft reactor, retort	simple design long residence times attainable semicontinuous operation	ore dressing autothermal coal gasification (Lurgi pressure gasification) thermal production of activated carbon chlorination of scrap iron to $FeCl_3$ reduction of copper compounds with HCl and H_2 to CuCl production of CS_2 from wood charcoal and sulfur vapor
Moving-bed reactor	long residence times attainable continuous operation heat supplied with gas stream	flue-gas desulfurization coal carbonization and coking (Lurgi purge-gas process) oil-shale retorting
Multiple-hearth reactor	for very long residence times individual hearths can be heated directly continuous operation gas can flow cocurrently or countercurrently small quantities of gas possible	roasting and reduction of ores production of activated carbon
Rotary kiln	relatively complicated design for long residence times direct heating possible continuous operation gas can flow cocurrently or countercurrently	roasting of ores production of calcium cyanamide from nitrogen and calcium carbide production of nickel carbonyl production of activated carbon production of ZnO from zinc burning of sulfur to SO_2
Fluidized-bed reactor	use of fine particles with narrow size distribution advantageous conditions can be made close to isothermal residence time controllable over a wide range entrainment of abraded material with gas stream necessitates downstream dust recovery step multistage operation and solids circulation possible use of supplemental solid heat-transfer agents possible high throughputs possible	burning of carbon for energy production autothermal coal gasification in Winkler generator in Ruhrgas process allothermal coal gasification (with solid heat-transfer agents) carbonization and coking fluidized-bed process Lurgi-Ruhrgas sulfur process roasting of ores chlorination of ores and lime production of activated carbon production of AlF_3 from Al_2O_3 and HF (multistage)
Entrained-flow reactor	solids in dust form with very narrow grain-size distribution very short residence time suspended dust can be conveyed with or without recycle for high throughputs internals for heat recovery by steam generation	carbonization and coking of coals (entrained-solids carbonization process) suspension smelting for beneficiation of copper and nickel ores (INCO process) coal gasification in Koppers–Totzek process in Prenflo process in Shell process
Dust roasters	very fine particles with narrow size distribution must be used solids drop downward velocity and residence time are governed by ratio of gravity to resistance force	ore roasting

(rods, strips, etc.) are used for this purpose. A much more efficient method, however, is direct , electric heating. Options here include arc, resistance, and induction heating.

The very high temperatures produced by the arc cause ionization in gases and thus activate the reactants; this feature is utilized in *plasma processes* for high-tempera-

Table 12. Reactors for noncatalytic liquid – solid reactions

Reactor type	Features	Examples of applications
Stirred tank	batch or semicontinuous operation predominant solids content limited by power of stirring apparatus	production of alkali cellulose and nitrocellulose reduction of nitrobenzene with metals to aniline or hydrazobenzene bauxite digestion production of salicylic acid from dry sodium phenolate (Kolbe – Schmitt process) hydrolysis of calcium cyanamide to cyanamide production of BF_3 from B_2O_3, CaF_2, and H_2SO_4 production of alkylaluminums from aluminum, olefin, and hydrogen production of tetraethyllead
Cascade of stirred tanks	for low reaction rates and high final conversions	apatite digestion
Tank with liquid recirculation	semicontinuous operation with solids fixed in tank and liquid recirculating	cellulose digestion production of ammonium sulfate from ammonium carbonate and gypsum
Rotary drum	for batch operation, high solids content	production of cellulose acetate and cellulose ethers production of AlF_3 by wet process
Fluidized-bed reactor	Semicontinuous operation intensive liquid circulation	water treatment
Steeping press	combination of reaction and liquid separation batch operation	production of cellulose ether
Kneader	used for highly viscous media	production of nitrocellulose, cellulose ether, and cellulose acetate
	for batch operation	production of celluloid from nitrocellulose production of superphosphate
Screw-conveyor reactor	used for highly viscous media batch operation	digestion of rutile or ilmenite with H_2SO_4
Multiple-hearth reactor	continuous operation long solids residence time	production of acetylene from carbide (dry gas generator)
Rotary kiln	direct heating for high reaction temperatures	digestion of fluorspar or phosphate with H_2SO_4reducing decomposition of H_2SO_4 in presence of carbon

Table 13. Reactors for noncatalytic solid-phase reactions

Reactor type	Features	Examples of applications
Shaft reactor	see Table 11	metallurgical processes, e.g., powder boriding of iron-based materials direct reduction of iron ores with carbon (Kinglor – Metor process)
Multiple-hearth reactor	see Table 11	calcination
Rotary kiln	see Table 11	cement production burning of lime, dolomite, gypsum, and magnesite calcination thermal decomposition of $FeSO_4$ and $BaCO_3$ reduction of barite with carbon to BaS reduction of ores with carbon (e.g., to ZnO)
Fluidized-bed reactor	see Table 11	burning of lime (multistage)

ture pyrolysis (→ Plasma Reactions, Chap. 2.1.; → Metallurgical Furnaces, Chap. 5.5.).

Equipment used for *solid reactions* includes arc and resistance-heated reduction furnaces and the Acheson furnace (→ Metallurgical Furnaces, Chap. 5.2., → Metallurgical Furnaces, Chap. 5.3.). The Acheson furnace is a resistance-heated device for pure solid – solid reactions; that is, in contrast to other processes, no melting of the solid charge occurs. All electrothermal processes are characterized by very high equipment cost and high electric power consumption. The prerequisite for their economical operation is a low unit price for energy.

This group of reactors and their applications are summarized in Table 14 and Figure 14.

3.7. Reactors for Electrochemical Processes (→ Electrochemistry; → Metallurgical Furnaces, Chap. 5.7.)

In electrochemical reactions, electrons are supplied to a reactant in the electrolyte or re-moved from it with the aid of an electric current. A minimum voltage called the decomposition voltage must be applied to the electrodes for this purpose. In addition to the electrochemical reactions occurring on the electrode surface, transport processes and chemical reactions in the electrolyte bath are important.

Electrochemical processes have the following advantages:

1) High product purity (no secondary reactions)
2) Low reaction temperature (except for fused-salt electrolysis)
3) Easy control of reaction rate through variation of electrode voltage

They have the following disadvantages:

1) High energy losses in the system
2) Large space requirements
3) High investment costs

For these reasons, electrochemical processes are used only when no available thermal or catalytic process can accomplish the same purpose, which is especially true in the production of chlorine, aluminum, and copper. A survey of important applications for electrolytic processes is given in the following:

Table 14. Electrothermal reactors

Reactor type	Features	Examples of applications
Plasma torch	very high temperature for plasma generation very short residence times large product spectrum	high-temperature pyrolysis for the production of acetylene and ethylene are furnace, Hüls d.c. torch, Hüls a.c. plasma torch, Höchst
Fluohm reactor	resistance heating with graphite fluidized bed	production of hydrogen cyanide (Shawinigan process)
Reduction arc furnace	very high reaction temperatures continuous raw material feed and periodic discharge or batch process	production of calcium carbide production of phosphorus decomposition of $BaCO_3$ production of corundum metallurgical processes (e.g., production of ferroalloys)
Reduction resistance furnace	for low temperatures and lower specific electrical power than the arc furnace	production of glass melts metallurgical processes (e.g., reduction of metal oxides) chlorinating digestion of rare-earth ores
Acheson furnace	reaction takes place in the solid phase batch process very long residence times	production of graphite production of silicon carbide
Reactor with indirect electric heating		azotization of carbide in a furnace with heating elements production of $MgCl_2$ from MgO in a blast furnace with electric heating

Chlorine production by chlor–alkali electrolysis
- Mercury amalgam process
- Diaphragm-cell process
- Membrane process

Metal winning by fused-salt electrolysis
- Aluminum
- Magnesium
- Sodium

Metal refining
- Copper
- Nickel

Electrolysis of inorganic materials
- Electrolysis of water
- Fluorine production by electrolysis of hydrogen fluoride
- Production of sodium chlorate by electrolysis of sodium chloride
- Electrochemical oxidation of sodium chlorate to perchlorate
- Recovery of persulfuric acid
- Production of ozone

Electrolysis of organic materials
- Production of adiponitrile from acrylonitrile
- Production of dimethyl sebacate
- Reduction of nitrobenzene to aniline
- Production of perfluorocaprylic acid
- Production of dihydrostreptomycin

The design of the reaction system (i.e., cell geometry and flow configuration), the electrode arrangement and material, and control of phases and concentrations are highly process specific.

Typical designs are illustrated in Figure 15.

3.8. Reactors for Biochemical Processes

(→ Biochemical Engineering;
→ Biotechnology)

Some important biochemical processes, such as those used in making beer, wine, alcohol, and baker's yeast, have been known for centuries. Typical of these reactions is their use of enzymes as biocatalysts. The enzymes can be present as cell constituents of living microorganisms, or they can be isolated in dissolved form or bound to inert supports (→ Immobilized Biocatalysts). The prerequisite for the use of live microorganisms is the provision of favorable living conditions. Such conditions include the presence of optimal amounts of nutrients and oxygen (in aerobic processes); maintenance of the temperature, pressure, maintenance of pH in certain ranges, and sterile conditions.

Figure 14. Reactors for electrothermal processes
A) Plasma torch; B) Fluohm reactor; C) Arc-heated reduction furnace; D) Resistance-heated reduction furnace; E) Acheson furnace; F) Reactor with indirect electric heating
a) Solids; b) Molten product; c) Gaseous reaction mixture; d) Gaseous product; e) Catalyst; f) Carrier gas; g) Electrodes; h) Plasma; i) Slag; j) Resistive charge; k) Off-gas

In addition to these factors, metabolism is important for reactor design. Aerobic processes require an adequate supply of oxygen. In anaerobic processes, the admission of gas from outside must be prevented; gases and solvent vapors resulting from the reaction must also be removed from the reactor.

Reactors for these processes can be classified as follows:

1) Reactors with dissolved or suspended biocatalysts (submerged processes) for aerobic or anaerobic conditions
2) Reactors with immobilized biocatalysts for aerobic or anaerobic conditions

Reactors for use in *submerged aerobic processes* have provisions for efficient aeration and intensive liquid circulation. Aeration is accomplished with fixed or moving distributors, nozzles, or submerged or rotating jets. Liquid circulation is ensured by various stirring systems or by forced or natural convection.

A summary of the most important reactor types and their applications is given in Table 15 and Figure 16.

Reactors for *anaerobic conditions* do not have aeration equipment. Usually, sealed vessels with or without stirrers are used (fermenters). Applications of these reactor types include fermentation processes (e.g., lactic acid fermentation, alcohol production, mash fermentation).

The *immobilization of enzymes* on suitable supports enables the use of reactor designs similar to those for heterogeneous catalytic processes. If the enzymes are supported on semipermeable membranes, separation and reaction can be combined in membrane reactors.

Reactors with immobilized biocatalysts, together with their applications, are listed in Table 16 and Figure 17.

3.9. Reactors for Photochemical and Radiochemical Processes

The photochemical and radiochemical principles are used to a very limited extent in industry because conditions for economical operation (e.g., high quantum efficiency) are seldom met.

3.9.1. Photochemical Reactors
(→ Photochemistry, Chap. 3.)

The rate of a photochemical reaction is determined by the concentration of reactants and by the intensity, quantity, and wavelength of light supplied. Light in the wavelength range that is absorbed by the reaction mixture can be formally

Figure 15. Reactors for electrochemical processes

treated as a reactant. As a consequence, photochemical reactions exhibit a position dependence of the reaction rate, even with complete mixing, because the flux density of light quanta decreases with increasing distance from the light source. The feasible thickness of the reaction space, and thus the type and size of reactor that can be used, depend not only on the power of the emitter, but also on the optical properties of the reactor material and the reaction medium. In-

Table 15. Reactors for submerged aerobic processes

Reactor type	Features	Examples of applications
Sparged stirred tank	various stirring and circulation apparatus suitable for higher viscosities	production of antibiotics amino acids yeast
Reactors with forced circulation		
Bubble column	very broad residence-time distribution good dispersion properties	production of yeast aerobic wastewater treatment
Jet reactor	free jet, jet nozzle, or central tube designs possible for low viscosities high gas velocities, good mass transfer	
Submerged-jet reactor	very broad residence-time distribution good mass transfer danger of slime settling out	processing of spent sulfite liquor fermentation of waste substrates
Reactors with natural circulation		
Bubble column	much backmixing, broad residence-time distribution for low viscosities simple construction	production of biomass citric acid
Loop reactor	for low viscosities little dispersive action	
Sieve-tray tower	good mass transfer due to fine bubble structures	
Surface reactors		
Trickle-bed reactor	low mass-transfer coefficients and negligible dispersive action	production of acetic acid aerobic wastewater treatment
Reactor with rotating internals	use of paddles, cylinders, etc. suitable for viscous media	aerobic wastewater treatment

Table 16. Reactors for biochemical processes over immobilized biocatalysts (for aerobic and anaerobic conditions)

Reactor type	Features	Examples of applications
Fixed-bed reactor	high conversions possible high catalyst density danger of uneven flow through system combined with poor mass transfer high mechanical stress on catalyst large pressure drop simple design	production of amino acids fructose ethanol wastewater treatment
Stirred tank with suspended catalyst	continuous or batch operation good conditions for external mass transport only partial conversion achievable mechanical stress on catalyst grains due to shear forces possibility of continuous catalyst replacement	production of fructose
Fluidized-bed reactor	good conditions for external mass transport possibility of continuous catalyst replacement low catalyst concentration high flow velocities necessary	production of enzymes ethanol wastewater treatment
Membrane reactor	various membrane configurations possible catalyst separated from substrate capacity limited by transport resistance of membranes aging and fouling of membranes large pressure drop	production of enzymes pharmaceuticals amino acids

tensive mixing must be ensured, especially for thick beds. Light can be supplied from outside (through the reactor wall) or by submerged light sources. When high-power light sources are used a large amount of heat is evolved and supplemental cooling devices must be employed.

A survey of reactor types and their industrial applications appears in Table 17 and Figure 18.

3.9.2. Radiochemical Reactors (→ Radiation Chemistry)

Radiochemical reactions are induced by the action of ionizing radiation. In addition to high energy consumption, the extremely complex design of radiation sources and shielding works against the wider use of this reaction principle.

The following are known applications:

1) Production of ethyl bromide (Dow process, Fig. 19)
2) Radiative cross-linking of poly(vinyl chloride) and polyethylene
3) Production of alkyltin compounds
4) Degradation of polymers

Some reactions, such as chlorinations, can be implemented in either photochemical or radiochemical form.

Table 17. Reactors for photochemical processes

Reactor type	Features	Examples of applications
Tubular reactor	for homogeneous gas- and liquid-phase reactions	chlorination of benzene to hexachlorocyclohexane sulfochlorination chlorination of methane to dichloromethane
Bubble column	requires favorable optical conditions and low viscosity also used in cascades and with central tube	sulfochlorination of paraffins (cascade) side-chain chlorination of aromatics production of dodecanethiol from 1-dodecene and H_2S
Stirred tank	optically induced differences in reaction rate equalized by intensive stirring	oximation of cyclohexane with nitrosyl chloride production of provitamin D_3
Falling-film reactor	suitable for poor optical conditions because film is very thin	production of vitamin D_2
Belt reactor	especially for highly viscous media	polymerization to PAN, PAC, PVC, PVAC ∗

∗ PAN = polyacrylonitrile; PAC = polyacrylate; PVC = poly(vinyl chloride); PVAC = poly(vinyl acetate).

n	output of the nth tank reactor in a cascade, or of a segment n
r	reaction, radial direction
s	solid
S	solid phase
t	transverse
v	volumetric
w	wall
z	axial direction

1. Introduction

Reactor modeling represents a simultaneous solution and analysis of mass, energy, and momentum transfer equations along with reaction rate and equilibrium data. Sometimes additional information (e.g., of economic nature in reactor optimization calculations) must be also included in the reactor model.

Important goals of reactor modeling are [1]:

1) Scale-up of experimental laboratory units to pilot-plant size
2) Scale-up of pilot-plant units to full scale size
3) Prediction of behavior of different reactor feedstocks and new catalysts
4) Prediction of transients in reactors for better control
5) Optimization of steady-state operating conditions
6) Better understanding of the system that may lead to process and design improvements

Reactor modeling in the hands of a practitioner is a powerful tool and can result in faster, more economical process design. It should always be coupled with pilot-plant experiments and process development.

The most important parts of reactor modeling are described in this article; namely, simulation of batch and continuous stirred-tank reactors, tubular systems, and packed beds. Some elements of optimization of chemical reactors are presented as well.

2. Batch Reactors

2.1. Homogeneous Systems

2.1.1. Isothermal Reactors

Batch reactors are usually operated as closed systems with no net inflow or outflow of mass. The systems are also well-mixed and no spatial gradients exist. The *material balance* for a component J in a batch reactor which meets these conditions, is:

$$\frac{dm_{\mathrm{J}}}{\mathrm{d}t} = m\frac{\mathrm{d}\xi_{\mathrm{J}}}{\mathrm{d}t} = M_{\mathrm{J}}\, R_{\mathrm{J}} V_{\mathrm{r}} \tag{2.1}$$

where V_{r} is the volume of the reaction mixture, m the total mass of the system (kg), m_{J} the mass of component J in the system (kg), ξ_{J} the degree of conversion of J, M_{J} the molar mass of component J (kg/kmol), and R_{J} the molar rate of production of J per unit volume of the reaction phase (kmol m^{-3} s^{-1}). In the isothermal case, R_{J} is only a function of the reactants for an irreversible reaction or a function of reactants and products for a reversible reaction. In terms of the density of the reaction mixture, $\varrho = m/V_{\mathrm{r}}$, the material balance can be written in integral form (Eq. 2.2) and the reaction time t that is required for a certain degree of conversion can be obtained by integrating Equation (2.1).

$$t = \int_0^{\xi_{\mathrm{J}}} \frac{\varrho\, \mathrm{d}\xi_{\mathrm{J}}}{M_{\mathrm{J}} R_{\mathrm{J}}} \tag{2.2}$$

If the density of the reaction mixture remains constant during the course of the reaction, the integration is simplified. In the case of *irreversible nth-order reactions* integration gives

$$t = \frac{(1-\xi_{\mathrm{J}})^{1-n} - 1}{k\,(n-1)\, c_{\mathrm{J}_0}^{n-1}}, n \neq 1. \tag{2.3}$$

$$t = \frac{\ln\,(1-\xi_{\mathrm{J}})}{-k}, n = 1 \tag{2.4}$$

The rate equations of *reversible first-order reactions* with initial concentrations c_{J_0} and c_{P_0} and rate constants k_1 and k_2 for the forward and backward reactions respectively, can also be integrated:

$$t = \frac{\ln\left[(1-\xi_{\mathrm{J}})\,(k_1+k_2) - k_2 \frac{c_{\mathrm{J}_0}+c_{\mathrm{P}0}}{c_{\mathrm{J}0}}\right]}{-\,(k_1+k_2)} \tag{2.5}$$

The general problem in reactor design is to calculate the volume of a reactor for a certain average rate of production. The volume can be obtained from the required degree of conversion and the corresponding reaction times. In batch operation, a certain time is used for filling, heating, cooling, and cleaning and during this time no production occurs. If t' denotes this off-line time and Φ_{P} denotes the desired production of product P, the reactor volume is

$$V_{\mathrm{R}} = \frac{\nu_{\mathrm{A}} \Phi_{\mathrm{P}}\,(t+t')}{\nu_{\mathrm{P}} M_{\mathrm{P}} c_{\mathrm{A}_0} \xi_{\mathrm{A}}} \tag{2.6}$$

where ν_{A} and ν_{P} are the stoichiometric coefficients of reactant A and product P, respectively.

2.1.2. Nonisothermal Reactors

All chemical reactions are accompanied by evolution or absorption of heat. The most important considerations which determine the choice of temperature in the reactor are:

1) Chemical equilibrium and the conversion rate of the desired reaction; the maximum conversion of a reversible exothermic reaction is reduced when the temperature is increased, but the kinetic rate increases, therefore an optimum temperature exists.
2) Undesirable side reactions (which also depend on temperature and their role in the overall equilibrium) can influence the maximum yield of product.
3) Phase transformations of reactants or products; there are examples where it is better to carry out the reaction in the liquid instead of the gaseous phase to achieve maximum conversion and mass transfer. An example is the formation of methyl *tert*-butyl ether from isobutene and methanol.
4) Cost implications of heating reactants to the reacting temperature; energy cost must be compared with the gain in yield at increased temperature as maximum yield and maximum profitability will not always be at the same temperature [2].

Constant Pressure. At constant pressure, the energy balance in a well-mixed batch reactor is:

$$\varrho c_p \frac{\mathrm{d}T}{\mathrm{d}t} + (\Delta H_\mathrm{r})_\mathrm{J}\, R_\mathrm{J} = \frac{\dot{Q}}{V_\mathrm{r}} \tag{2.7}$$

where c_p denotes the specific heat capacity, $(\Delta H_\mathrm{r})_\mathrm{J}$ the reaction enthalpy for the conversion of or to one molar unit of J, and $\dot{Q}$ denotes the rate of heat flow to or from the reactor. In the case of adiabatic operation, $\dot{Q} = 0$. Otherwise, $\dot{Q}$ can be determined as follows:

$$\dot{Q} = hA\left(T - T_{\mathrm{c,H}}\right) \tag{2.8}$$

where h is the overall heat-transfer coefficient and A the heat-transfer area. The external temperature can be cooler (T_c) or hotter (T_H) than T, depending on whether cooling or heating must be accomplished. The overall heat-transfer coefficient h is calculated from correlations [3] and it depends on the temperature of the cooling or heating medium. Thus, a heat-transfer coefficient $h_{\mathrm{a}v}$ is calculated at the average medium temperature. If Φ_m is the mass flow rate and $c_{p\mathrm{m}}$ is the specific heat capacity of the cooling or heating medium, then h is corrected according to:

$$h = \frac{h_{\mathrm{a}v}}{1 + \frac{h_{\mathrm{a}v} A}{2\,\Phi_\mathrm{m}\, c_{p\mathrm{m}}}} \tag{2.9}$$

Example. In a batch reactor with a volume of $5\,\mathrm{m}^3$, an exothermic reaction $\mathrm{A} \rightarrow \mathrm{P}$ is carried out in the liquid phase. The density of the mixture does not change during the reaction. The rate of reaction is given by

$$R_\mathrm{A} = -k c_\mathrm{A}$$

with $k = 4 \times 10^6 \exp(-7500/T)\,\mathrm{s}^{-1}$. The heat of reaction is $(-\Delta H_\mathrm{r})_\mathrm{A} = 1.67 \times 10^6$ J/kg, the initial concentration of A is $c_{\mathrm{A}_0} = 1$ kmol/m^3, $M_\mathrm{A} = 100$ kg/kmol and $\varrho C_p = 4.2 \times 10^6\,\mathrm{J\,m^{-3}\,K^{-1}}$. The initial temperature of the reaction mixture is 298 K. The reactor is fitted with a heat-exchange coil with a surface area of $3.3\,\mathrm{m}^2$. The heat exchanger is operated with steam ($T_\mathrm{H} = 393$ K, $h = 1000\,\mathrm{W\,m^{-2}\,K^{-1}}$) and with cooling water ($T_\mathrm{c} = 290$ K, $h = 1400\,\mathrm{W\,m^{-2}\,K^{-1}}$). Filling and emptying of the reactor take 600 s and 900 s, respectively.

For a required conversion $\xi_\mathrm{A} \geq 0.95$, the temperature profile over one reaction cycle and the duration of a reaction cycle shall be determined when the following policy of operation is followed: heat up to 350 K, the reaction then proceds under isothermal conditions until $\xi_\mathrm{A} = 0.95$, followed by cooling down to 310 K.

Solution. The following equations must be solved simultaneously for the first part of the reaction cycle:

$$\frac{\mathrm{d}\xi_\mathrm{A}}{\mathrm{d}t} = k\,(1 - \xi_\mathrm{A})$$

$$\varrho c_p \frac{\mathrm{d}T}{\mathrm{d}t} = (-\Delta H_\mathrm{r})_\mathrm{A}\, c_{\mathrm{A}_0} M_\mathrm{A}\, k\,(1 - \xi_\mathrm{A}) + \frac{hA_\mathrm{s}}{V_\mathrm{r}}\,[T_\mathrm{s} - T]$$

Starting from the initial concentration and temperature, a small temperature interval ΔT is selected. Average values for T and k over this interval are then calculated and used together with the initial value for ξ in the second equation to solve for Δt. This value is then used in the first equation to solve for ξ. An average value for ξ over this interval can then be calculated. With the average values of T, k, and ξ, an improved Δt value can be calculated from the second equation and the process is repeated until the required degree

of accuracy is reached. In Figure 1 the temperature profile is shown. Once the conversion is 0.95, cooling commences. The cooling period can be calculated by integrating the following energy equation from $T = 350$ K to $T = 310$ K:

$$\varrho c_p \frac{\mathrm{d}T}{\mathrm{d}t} = (-\Delta H_\mathrm{r})_\mathrm{A}\, c_{\mathrm{A}_0} M_\mathrm{A} k\,(1-\xi_\mathrm{A}) + \frac{hA_\mathrm{c}}{V_\mathrm{r}}\,[T_\mathrm{c} - T]$$

Integrating the first two equations from the initial conditions until T is 350 K gives a preheating period of 2384 s. The temperature is then kept constant and only the first equation is integrated until the conversion reaches 0.95; this period takes 1000 s. For the cooling-off period the third equation is integrated and this gives 5426 s. Adding 1500 s for filling and emptying gives a total period of one cycle of 10 310 s.

Figure 1. Temperature profile over a reaction cycle

Constant Volume. The energy balance for a constant volume process is

$$\varrho c_v \frac{\mathrm{d}T}{\mathrm{d}t} + (\Delta U_\mathrm{r})_\mathrm{J}\, R_\mathrm{J} = \frac{\dot{Q}}{V_\mathrm{r}} \tag{2.10}$$

Since ΔU_r is the change of internal energy at constant volume and temperature, for the case of an ideal gas ΔH_r and ΔU_r are related as follows:

$$\Delta H_\mathrm{r} = \Delta U_\mathrm{r} + RT\,\Delta n \tag{2.11}$$

This relation will be different for reaction mixtures with another equation of state.

Example. A closed tank with an internal volume of 250 m^3 contains a mixture of air with 4 % butane at 18 °C and a pressure of 100 kPa. The mixture is ignited and the reaction proceeds according to:

$$\mathrm{C_4H_{10}} + 6.5\,\mathrm{O_2} \rightarrow 4\,\mathrm{CO_2} + 5\,\mathrm{H_2O}$$

The heat of combustion at 18 °C and 100 kPa is $(-\Delta H_\mathrm{r}) = 2880$ kJ/mol. The pressure in the vessel shall be determined after the explosion.

Solution. Since the reaction proceeds adiabatically and at constant volume, the total internal energy of the reaction mixture does not change. The temperature rise is calculated from:

$$\int_{T_0}^{T} c_v\,\mathrm{d}T + \int_{\xi_{\mathrm{B}_0}}^{\xi_\mathrm{B}} \frac{(\Delta U_\mathrm{r})_\mathrm{B}}{M_\mathrm{B}}\,\mathrm{d}\xi_\mathrm{B} = 0$$

where the index B denotes butane.

To calculate $(\Delta U_\mathrm{r})_\mathrm{B}$, the relationship between U and H and the ideal gas law will be used:

$$\Delta H_\mathrm{r} = \Delta U_\mathrm{r} + RT\,\Delta n$$

The total change in number of moles is $(4 + 5 - 7.5 = 1.5)$, hence:

$$RT\,\Delta n = 1.5 \times 8.314\ \mathrm{J\,mol^{-1}\,K^{-1}} \times 291\ \mathrm{K} = 3.63 \times 10^3\ \mathrm{J/mol}$$

Since $\mathrm{O_2}$ is the limiting reactant (i.e., $\mathrm{O_2}$ is present in substoichiometric amounts), not all butane will react. The composition of the final mixture can then be calculated. In Table 1 the initial and final compositions are given. The specific heat capacity at constant volume (c_v) of the product mixture is a function of temperature and can be found in thermodynamic tables. In this example the average value of c_v is 1.06 kJ/kg. The mole fractions of butane before and after the reaction were 0.04 and 0.0089, respectively. These values can be converted to mass fractions by multiplying the mole fraction of each component in Table 1 by its molecular mass and normalizing. The mass fractions of butane before and after reaction are 0.077 and 0.017, respectively.

Table 1. Initial and final gas compositions

Compound	Mole fraction before reaction	Mole fraction after reaction
Butane	0.04	0.0089
Nitrogen	0.758	0.708
Oxygen	0.2028	
Carbon dioxide		0.182
Water		0.093

The temperature rise can now be determined:

$$c_v \times (T - T_0) + \left[\frac{(-\Delta H_\mathrm{r})_\mathrm{B} - RT\,\Delta n}{M_\mathrm{B}}\right] \times (\Delta\xi_\mathrm{B}) = 0$$

so:

$$\begin{aligned}&1.06\,\mathrm{kJ/kg} \times (T - 291\,\mathrm{K})\\&+\left(\frac{-2880\,\mathrm{kJ/mol} - 3.63\,\mathrm{kJ/mol}}{58\,\mathrm{g/mol}}\right)\\&\times (0.077 - 0.017) = 0\\&T = 3103\,\mathrm{K} = 2830\,^\circ\mathrm{C}\end{aligned}$$

Applying the ideal gas law, the pressure can be determined:

$$\begin{aligned}&P \times 250\,\mathrm{m}^3 = 1.046 \times n_0 \times 8.314\,\mathrm{J\,mol^{-1}\,K^{-1}}\\&\times (3103\,\mathrm{K}) = 1115.4\,\mathrm{kPa}\end{aligned}$$

where $1.046 \times n_0$ is the total number of moles present after the explosion. The last column in Table 1 is the mole fraction based on kmol/kmol original mixture and adding this column will give the relative change in the number of moles in the mixture.

2.2. Nonhomogeneous Systems

Batch systems are spatially homogeneous when the reactant mixture is well-mixed during the course of the reaction. Nonideal mixing can cause settling or separation of phases in liquid – gas mixtures, mixtures of nonmiscible liquids or liquid – solid mixtures. However, even reactants which are well-mixed, do not necessarily react in a homogeneous way. Even if a single phase is present, the system can still be spatially nonhomogeneous.

2.2.1. Gas – Liquid Reactions

In the following example, the design of a batch reactor, where both a liquid and a gas phase are present, will be demonstrated.

Example. A batch reactor must be designed for the production of 1×10^5 kg/day fats containing monounsaturated fatty acids by hydrogenation of cottonseed oil. The reaction is carried out on a nickel catalyst that is dispersed in hard stearin. Hydrogen is bubbled through the oil, thus two phases are present. The following equations describe the conversion and formation of acid moieties with diunsaturated (B), *cis*-monounsaturated (R_1), *trans*-monounsaturated (R_2), and saturated (S) aliphatic chains:

$$\begin{aligned}\frac{\mathrm{d}c_\mathrm{B}}{\mathrm{d}t} &= -(k_1 + k_2)\, c_{\mathrm{H_s}}^{0.5} c_\mathrm{B}\\ \frac{\mathrm{d}c_{\mathrm{R}_1}}{\mathrm{d}t} &= k_1 c_{\mathrm{H_s}}^{0.5} c_\mathrm{B} - k_3 c_{\mathrm{H_s}}^{0.5} c_{\mathrm{R}_1}\\ &\quad + k_4 c_{\mathrm{H_s}}^{0.5} c_{\mathrm{R}_2} - k_5 c_{\mathrm{H_s}} c_{\mathrm{R}_1}\\ \frac{\mathrm{d}c_{\mathrm{R}_2}}{\mathrm{d}t} &= k_2 c_{\mathrm{H_s}}^{0.5} c_\mathrm{B} + k_3 c_{\mathrm{H_s}}^{0.5} c_{\mathrm{R}_1}\\ &\quad - k_4 c_{\mathrm{H_s}}^{0.5} c_{\mathrm{R}_2} - k_6 c_{\mathrm{H_s}} c_{\mathrm{R}_2}\\ \frac{\mathrm{d}c_\mathrm{s}}{\mathrm{d}t} &= k_5 c_{\mathrm{H_s}} c_{\mathrm{R}_1} + k_6 c_{\mathrm{H_s}} c_{\mathrm{R}_2}\end{aligned}$$

The hydrogen concentration in the gas phase ($c_{\mathrm{H_i}}$) is in equilibrium with the hydrogen on the catalyst surface, $c_{\mathrm{H_s}}$. Since the gas is essentially pure hydrogen, $c_{\mathrm{H_i}}$ is constant. Furthermore it is assumed that the rate of consumption of adsorbed hydrogen on the catalyst surface is balanced by the rate of mass transfer from the gas phase. Let $K_\mathrm{D} = c_{\mathrm{H_s}}/c_{\mathrm{H_i}}$ denote the ratio between the two concentrations, then the following relation exists:

$$K_\mathrm{D}^{0.5} = \frac{-\left[1 + \frac{1}{s_2}\right][1 - \xi_\mathrm{B}]}{2\left(\frac{1}{\gamma} + \frac{Y_{\mathrm{R}_1}}{s_5} + \frac{Y_{\mathrm{R}_2}}{s_6}\right)} + \frac{\left[\left(1 + \frac{1}{s_2}\right)^2 (1 - \xi_\mathrm{B})^2 + \frac{4}{\gamma}\left(\frac{1}{\gamma} + \frac{Y_{\mathrm{R}_1}}{s_5} + \frac{Y_{\mathrm{R}_2}}{s_6}\right)\right]^{0.5}}{2\left(\frac{1}{\gamma} + \frac{Y_{\mathrm{R}_1}}{s_5} + \frac{Y_{\mathrm{R}_2}}{s_6}\right)}$$

where $Y_{\mathrm{R}_1} = c_{\mathrm{R}_1}/c_{\mathrm{B}_0}$, $Y_{\mathrm{R}_2} = c_{\mathrm{R}_2}/c_{\mathrm{B}_0}$, $\gamma = k_1 c_{\mathrm{B}_0}/K_\mathrm{L}\, a_v\, c_{\mathrm{H_i}}^{0.5}$, $s_2 = k_1/k_2$, $s_3 = k_1/k_3$, $s_4 = k_1/k_4$, $s_5 = k_1/k_5 c_{\mathrm{H_i}}^{0.5}$, $s_6 = k_1/k_6 c_{\mathrm{H_i}}^{0.5}$. The product of the mass-transfer coefficient and the bubble area a_v was determined experimentally as $K_\mathrm{L}\, a_v = 0.022\,\mathrm{s}^{-1}$. Whereas the s_i values denote the ratios of reaction rate constants, γ is a ratio between kinetic and mass transfer rates.

Experiments on the hydrogenation of cottonseed oil using a Rufert nickel catalyst gave the following values for the reaction rate constants [4]: $k_1 = 0.254\ \sqrt{\mathrm{L/mol}}/\mathrm{min}$, s_2= 2.89, s_3= 5.05, s_4= 15.1, s_5= 3.38, s_6= 3.38. The hydrogen concentration in the gas phase is $c_{\mathrm{H_i}}$ = 0.0129 mol/L. The feedstock composition (wt %) consists of 25.6 % S, 27 % R_1, 0.4 % R_2 and 47 % B. The molar concentration of B, c_{B} is 1.45 mol/L. The value for γ can now be calculated:

$$\gamma = \frac{0.254\ \sqrt{\mathrm{L/mol}}/\mathrm{min} \times 1.45\,\mathrm{mol/L}}{(60 \times 0.022)\ \mathrm{min}^{-1} \times 0.1136\ \sqrt{\mathrm{mol/L}}/\mathrm{min}} = 2.45$$

The reactions are irreversible, hence c_{s} does not appear in the rate expressions for components B, R_1, and R_2 and they can be integrated independently from the balancing equation for S. Time can be substituted in terms of the conversion of B:

$$\frac{\mathrm{d}Y_{\mathrm{R_1}}}{\mathrm{d}\xi_{\mathrm{B}}} = \frac{(1-\xi_{\mathrm{B}}) - \frac{Y_{\mathrm{R_1}}}{s_3} + \frac{Y_{\mathrm{R_2}}}{s_4} - \frac{Y_{\mathrm{R_1}}}{s_5} K_{\mathrm{D}}^{0.5}}{\left(1+\frac{1}{s_2}\right)(1-\xi_{\mathrm{B}})}$$

$$\frac{\mathrm{d}Y_{\mathrm{R_2}}}{\mathrm{d}\xi_{\mathrm{B}}} = \frac{\left(\frac{1-\xi_{\mathrm{B}}}{s_2}\right) - \frac{Y_{\mathrm{R_1}}}{s_3} + \frac{Y_{\mathrm{R_2}}}{s_4} - \frac{Y_{\mathrm{R_1}}}{s_5} K_{\mathrm{D}}^{0.5}}{\left(1+\frac{1}{s_2}\right)(1-\xi_{\mathrm{B}})}$$

These two equations, together with the algebraic equation for K_{D} can now be integrated, using the initial conditions $Y_{\mathrm{R_1}}$ = 27/47, $Y_{\mathrm{R_2}}$ = 0.4/47, and ξ_{B} = 0. In Figure 2 A, the total yield of monounsaturates is shown as a function of ξ_{B}. A maximum is obtained at ξ_{B} = 0.84 and the time it takes to obtain 84 % conversion of B is 115 min (see Fig. 2 B). The processing time, excluding the reaction time, is best ascerted from plant studies; for this example 2.5 h are taken. Hence the total time (conversion plus processing) is 4.42 h. Thus, five batches can be processed per day, each batch producing 20×10^3 kg. At 84 % conversion the product mixture consists of 67 kg monounsaturates per 100 kg of mixture, hence the reactor volume is:

$$V_{\mathrm{r}} = 1.05 \times \frac{100\,\mathrm{kg}}{67\,\mathrm{kg}} \times 20\,000\,\mathrm{kg} \times \frac{1}{800\,\mathrm{kg/m^3}} = 39.2\,\mathrm{m^3}$$

where the factor 1.05 is introduced because 5 % was added for head space and 800 kg/m^3 is the density of cottonseed oil. Using a height to diameter ratio of two, the specification of the vessel is 2.92×5.84 m.

Figure 2. Total yield of monounsaturates in the hydrogenation of cottonseed oil (A) and conversion time of diunsaturates (B)

2.2.2. Solid – Solid Reactions

Even when only one phase is present, the reaction can progress in a nonhomogeneous way. Reactions with large activation energies require a certain amount of preheating before they be-

gin. If the temperature profile in a batch system is not uniform, the reaction rate will also be spatially distributed and if the heat of reaction is large, it will further contribute to the concentration of high temperatures in local areas inside the reactor.

Solid – solid reactions that are associated with large activation energies and large heats of reaction often take place in the combustion mode. The combustion mode is associated with strong spatial gradients and modeling these type of reactions requires special techniques. Examples of solid – solid reactions which occur in the combustion mode are those between Ti and C, Mo and Si, and Ta and C. The well-mixed reactants are usually prepared as a preform that is ignited at one end of the sample (see Fig. 3). Once the combustion wave has traversed the length of the sample, the reaction is complete. Conversion is high in these combustion reactions and under ideal conditions complete conversion can be accomplished. Two factors determine the degree of conversion. If the system loses a lot of heat during the reaction, the degree of conversion drops. Thus, the closer the system can be operated to adiabatic conditions, the higher will be the degree of conversion. The second factor is incomplete mixing of the reactants. In these type of reactions it is important to have intimate contact between the different species on the micro-level. Therefore, mixing of the reactants is one of the most time- consuming and expensive steps in the process.

Figure 3. Typical configuration of solid – solid batch reactions

The mass and energy balances are

$$\frac{\partial c_{\mathrm{J}}}{\partial t} = -R_{\mathrm{J}} \tag{2.12}$$

$$\varrho c_p \frac{\partial T}{\partial t} = \nabla \cdot \lambda \nabla T + (-\Delta H_{\mathrm{r}})_{\mathrm{J}} R_{\mathrm{J}} \tag{2.13}$$

where λ denotes the thermal conductivity. Note that diffusion of the solid reactant is negligible. The geometry of the system is determined by the shape of the reactant mixture. A popular practice is to press the reactant mixture into a cylindrical preform. For this case, Equation (2.13) must be consistent with a cylindrical geometry, the dimensions of which are determined by the preform. The temperature at the reaction front can be very high and Equation (2.13) must be amended to take phase transformations into account. In the following section some aspects of the maximum temperature rise are discussed.

Maximum Temperature Rise. For $T_{\mathrm{ad}} < T_{\mathrm{fus}}$ the adiabatic temperature T_{ad} rise of a system where reactant A is transformed to product P, is given by:

$$T_{\mathrm{ad}} = T_0 + \frac{(-\Delta H_{\mathrm{r}})\, c_{\mathrm{A}}}{\varrho c_p} \tag{2.14}$$

When $T_{\mathrm{ad}} > T_{\mathrm{fus}}$ and

$(-\Delta H_{\mathrm{r}}) < \int_{T_0}^{T_{\mathrm{fus}}} c_p \mathrm{d}T + (-\Delta H_{\mathrm{fus}})$ the following equation holds:

$$T_{\mathrm{ad}} = T_0 + \frac{(-\Delta H_{\mathrm{r}})\, c_{\mathrm{A}}}{\varrho c_p} - \frac{\nu\,(-\Delta H_{\mathrm{fus}})}{c_p} \tag{2.15}$$

Otherwise:

$$T_{\mathrm{ad}} = T_{\mathrm{fus}} + \frac{(-\Delta H_{\mathrm{r}})\, c_{\mathrm{A}}}{\varrho c_{p\mathrm{l}}} - \frac{(-\Delta H_{\mathrm{fus}})}{c_{p\mathrm{l}}} - \frac{c_p}{c_{p\mathrm{l}}}\,[T_{\mathrm{fus}} - T_0] \tag{2.16}$$

where c_{p1} denotes the specific heat capacity of the liquid. Average properties over the temperature range must be used and the densities of the solid and liquid phases are assumed to be the same. The final temperature can be decreased by adding product to the reactant mixture to decrease c_{A}. There is a bound on the degree of dilution; if the system is too dilute, it will not ignite and self-propagation of the combustion front is not possible [5].

Equations (2.14) – (2.16) are derived on the basis of thermodynamic arguments, but the

batch process is transient and the maximum temperatures in the transient process can be different from those obtained from Equations (2.14) – (2.16). Unfortunately no rigorous bounds on the maximum temperature of a transient process are known and they must be determined by numerical methods. Furthermore, these transient maxima can exceed the adiabatic temperature and Equations (2.14) – (2.16) cannot be relied upon to give upper estimates of the reaction temperature.

Figure 4. Temperature at the center of the cylindrical TiC sample

Example. Determine the maximum temperature of the following reaction:

$$\mathrm{Ti} + \mathrm{C} \rightarrow \mathrm{TiC}$$

A stoichiometric mixture of the reactants is pressed into a cylinder and simultaneously ignited at both ends. The cylinder is 2 cm long and perfectly insulated. The necessary properties of the system are listed below:

Density	$3240\,\mathrm{kg/m^3}$
Heat capacity	$1113.48\,\mathrm{J\,kg^{-1}\,K^{-1}}$
Thermal conductivity	$8.37\,\mathrm{W\,m^{-1}\,K^{-1}}$
Heat of formation at 25 °C	1.84×10^5 J/mol
Activation energy of formation reaction	8.29×10^5 J/mol
Frequency factor in expression for rate constant of formation reaction	$1.05\times10^5\,\mathrm{s^{-1}}$

Solution. Equations (2.12), (2.13) are integrated numerically and the maximum temperature at the center of the Ti – C cylinder is shown in Figure 4. The adiabatic temperature for this reaction is obtained from Equation (2.14):

$$T_{\mathrm{ad}} = 298\,\mathrm{K} + \frac{\left(1.8\times10^8\right)\ \mathrm{J/kmol}}{60\,\mathrm{kg/kmol}\times1113.48\,\mathrm{J\,kg^{-1}\,K^{-1}}} = 3052\,\mathrm{K}$$

The maximum transient temperature is 5100 K. The temperature overshoot is 2000 K. Since the melting point of TiC is 3420 K, the transient maximum temperature will exceed the melting point.

Reaction Wave Propagation. When the sample is ignited at one point by an external heat source, the reaction front can traverse the sample in a number of ways. The ideal propagation mode, from a processing point of view, is a stable front that propagates at a constant speed. If this front velocity is denoted by v_{F}, a similarity transformation can be made between time t and the direction of propagation x to render Equations (2.12), (2.13) time independent:

$$z = x + v_{\mathrm{F}}\,t \tag{2.17}$$

The integrity of this planar front is not preserved when external heat losses are present. Heat losses also reduce v_{F}. If heat losses are large enough, the system is quenched.

Other modes of front propagation also exist [6]. The planar front can, for example, become unstable and collapse into hot spots which are seated at different positions from the centerline. These hot spots propagate in a helical way around the centerline, leaving behind regions of incomplete conversion.

2.2.3. Solid – Gas Reactions

In solid – gas systems, combustion takes place between a solid and a gaseous component. A very important factor is the flow of gas through the porous solid by means of filtration or permeation. Hence this type of reaction is often termed *filtration combustion*. In Figure 5 various configurations for filtration combustion are shown.

Figure 5. Different configurations of batch solid – gas reactions
A) Reaction initiated at top of container; B) Reaction initiated from bottom of container; C) Free-standing sample with gas penetrating from all sides; D) Design with both counter- and crossflow of reactant gases towards reaction front

The first two configurations are similar. In Figure 5 A, the reaction was initiated at the top of the container and the front propagates away from the open end. In Figure 5 B the reaction was initiated at the bottom of the container and the front propagates countercurrently to the flow of gas. An advantage of the second option is that the diffusion length for the gas decreases with increasing degree of conversion. Product materials also tend to sinter partially during the reaction, which makes them less permeable than the fresh material, which is another advantage of the second configuration. The sample shown in Figure 5 C is free standing and gas can penetrate from all sides into the sample. However, the reactant powder must be compressed to give the sample the necessary strength, therefore the powder's permeability will decrease. The configuration depicted in Figure 5 D is the most practical, because both counter- and crossflow of reactant gases towards the reaction front can be maintained without limiting the flow of the gaseous reactant through the solid medium. The filtration combustion model is described by the following set of equations:

$$\frac{\partial \varepsilon \varrho_{\mathrm{g}}}{\partial t} = -\nabla\left(\varepsilon \varrho_{\mathrm{g}} v\right) - \nu_{\mathrm{g}} R_{\mathrm{s}} \tag{2.18}$$

$$\frac{\partial\left[\varepsilon \varrho_{\mathrm{g}} c_{pg} + (1-\varepsilon)\, \varrho_{\mathrm{s}} c_{ps}\right]}{\partial t} = \nabla \cdot \nabla\left(\lambda T\right) - \nabla\left(\varepsilon \varrho_{\mathrm{g}} v T\right) + \left(-\Delta H\right)_{\mathrm{s}} R_{\mathrm{s}} \tag{2.19}$$

$$p = \frac{\varrho_{\mathrm{g}} R T}{M_{\mathrm{g}}} \tag{2.20}$$

$$v = -P \boldsymbol{\nabla} p \tag{2.21}$$

$$R_{\mathrm{g}} = -\varrho_{\mathrm{B}}^{0} p^{n} f\left(c_{\mathrm{s}}\right) k \tag{2.22}$$

where ε is the porosity of the bed, P the permeability in the bed, ϱ_{B}^{0} the initial bulk density of the solid, and $f\left(c_{\mathrm{s}}\right)$ the dependence of the reaction on the concentration of the solid phase. The porosity and permeability of the bed change as the reaction progresses, mainly because of sintering and melting; this affects the flow of gas to the front. The effects of sintering and melting can be incorporated into the model.

Example. A rectangular container is filled with titanium powder and placed in a chamber filled with nitrogen. The reaction is ignited at the top right of the container and the pressure in the chamber is kept constant. Low and high chamber pressures affect the conversion and in Figure 6 the results for both cases at different times (time increases from top to bottom) are shown.

The front propagates faster when the overhead pressure is higher and penetrates to the bottom of the container. When the overhead pressure is lower, conversion is incomplete and the

Figure 6. Conversion contours at different reaction times (time increases in the direction a – c) for A) low and B) high chamber pressures

reaction time is also much longer. When the depth of the container is increased, the chamber pressure must be further increased, but the exact values required can only be established through a numerical simulation.

3. Continuous Stirred-Tank Reactors (CSTR)

3.1. Isothermal Homogeneous System

The continuous, ideally mixed, stirred-tank reactor (CISTR) is a flow reactor in which all elements of the fluid have the same composition as the outlet stream of the reactor.

The continuous stirred-tank reactor is normally run at steady state, and is usually operated such that it is well-mixed. As a result, the CISTR is generally modeled as having no spatial variations in concentration, temperature, or reaction rate throughout the vessel. In systems where mixing is highly nonideal, the well-mixed model is inadequate and other techniques, such as residence-time distributions, have to be used to obtain meaningful results.

The CISTR has the following unique characteristics:

1) Temperature and heat transfer can be relatively easily controlled
2) Fine catalyst particles can be effectively suspended in a liquid reacting system
3) In a system with parallel reactions, a reaction with lower order is favored
4) In polymerization reactions, wider molecular mass distributions are expected
5) Very economical when long residence time is required
6) Recommended for liquid rather than gaseous reacting systems

Material Balance. The overall material balance for a CISTR which is schematically shown in Figure 7 reads:

$$\frac{d\,(m\xi_{\mathrm{J}})}{\mathrm{d}t} = -\Delta\Phi_{\mathrm{m}}\xi_{\mathrm{J}} + M_{\mathrm{J}}\,|R|_{\mathrm{J}}\,V_{\mathrm{r}} \tag{3.1}$$

where m is the total mass in the system; $-\Delta\Phi_{\mathrm{m}}$ the net inflow of mass by convection and diffusion; ξ_{J} the degree of conversion of component J; M_{J} — R —$_{\mathrm{J}}$ the mass rate of production of component J per unit volume; and V_{r} the volume of the reaction mixture.

Figure 7. CISTR reactor
For explanation of symbols see text

When a CISTR is operated in a steady state, the required reactor volume is

$$V_r = \Phi_m \frac{\xi_J}{M_J\,|R|_J} \tag{3.2}$$

or in the case of constant density

$$V_r = \Phi_v \frac{c_{J_0}\zeta_J}{R_J} \tag{3.3}$$

where Φ_v is the volumetric flow rate; ζ_J the relative degree of conversion; c_{J_0} the molar concentration of species J; and R_J the molar rate of production of J per unit volume of the reaction phase. The mass balance equations for various reaction orders are listed in Table 2.

Table 2. Ratio of outlet to inlet concentrations in a CISTR for reactions of different order

Reaction order, n	Reaction rate equation, R_A	Concentration ratio, c_A/c_{A_0}
-1	$k c_A^{-1}$	$\frac{1}{2}\left[1 + \sqrt{\left(1 - \frac{4k\tau}{c_{A_0}^2}\right)}\right]$
0	k	$1 - \frac{k\tau}{c_{A_0}}$
$\frac{1}{2}$	$k\sqrt{c_A}$	$\sqrt{\left(1 + \frac{k^2\tau^2}{4c_{A_0}}\right)} - \frac{k\tau}{2\sqrt{c_{A_0}}}$
1	$k c_A$	$\frac{1}{1+k\tau}$
2	$k c_A^2$	$\frac{1}{2k c_{A_0}\tau}\left\lvert\sqrt{(1 + 4k c_{A_0})} - 1\right\rvert$

Most important in designing a homogeneous CISTR system is to select equipment and stirring procedures that will assure essentially perfect mixing. Choice of a suitable type of impeller and reactor arrangement, the required power, the mode of adding and removing reactants and products, and the cooling or heating rates are all essential concerns. For more details, see → Stirring, [7], [8].

Mixing. For a processing vessel to be effective, the volume of fluid or slurry that is circulated by the impeller must be sufficient to sweep out the entire vessel in a reasonable time. Also, the velocity of the stream leaving the impeller must be high enough to carry the currents to the remotest parts of the tank. In addition, an adequate level of turbulence is required in order to maintain the high effectiveness of the process. The proper selection of an impeller, its speed, and the geometrical dimensions of the reactor are very important design parameters (→ Stirring; → Continuous Mixing of Fluids).

In practice, for moderately fast reactions, a tank reactor may be approximately considered as ideally mixed if the discharge rate of the impeller Φ_c (the circulation rate) is at least five to ten times the feed rate Φ_m i.e.,

$$\frac{\Phi_c}{\Phi_m} > 5 - 10 \tag{3.4}$$

The impeller discharge rate depends on the type of impeller, the tank geometry, and operating conditions. This discharge rate can be estimated from:

$$\frac{\Phi_c}{N d_I^3} = N_{QI} \tag{3.5}$$

where d_I is the impeller diameter, N the number of impeller revolutions per unit time, and N_{QI} is a dimensionless constant. The value of this constant depends on the axial blade width of the impeller, the number of blades, curvature or pitch, and the ratio of impeller velocity to fluid rotational velocity [8]. The following values are recommended for agitators in baffled tanks which are commonly used in industry:

Marine-Type Impeller:

$$N_{QI} = 0.5$$

Turbine (with six blades and width-to-diameter ratio of 1 : 5):

$$N_{QI} = 0.93 D/d_I \quad \text{for} \quad Re_{imp} > 10^4$$

where $Re_{imp} = \varrho N d_I^2/\mu$ is the impeller Reynolds number, and D the diameter of the reactor.

Many reactions require rapid dispersal of reactants in order to avoid even momentary build-up of high concentrations in the system. In homogeneous reacting systems, the most rapid dispersal can be accomplished by discharging the

feed as close as possible to the center of the impeller. Discharge ports for product removal should be located at the opposite end of the flow pattern from the inlet nozzle. In general, the flow of a reacting fluid through a reactor is a very complex process. The interaction of flow pattern and chemical reaction cannot be analyzed rigorously even in the simple case of a single isothermal reaction. Therefore simplified and/or idealized models are necessary.

Residence-Time Distribution (RTD). (→ Principles of Chemical Reaction Engineering, Chap. 4.2.1.). The frequency function often used in statistics (called the E diagram in RTD description) can be derived for a continuous stirred-tank reactor from a mass balance of the reactor with an ideal pulse perturbation at the inlet stream. The pulse is immediately distributed over the reactor, moreover the product concentration remains the same everywhere and equals the outlet concentration. The $E(t)$ diagram reads:

$$E(t) = \frac{1}{\tau} \mathrm{e}^{-t/\tau} \tag{3.6}$$

For a continuously operated mixing vessel which shows a RTD of an ideal mixer (Eq. 3.6), the different states of micromixing are (→ Principles of Chemical Reaction Engineering, Chap. 4.3.):

1) CISTR: the ideal mixer (mixing on molecular level)
2) CSSTR: the completely segregated mixer where the fluid consists of lumps which move through the reactor without exchange of matter with their surroundings
3) CSTR: the partially segregated mixer

A detailed description of the amount of micromixing with one parameter is generally not possible. For non-first-order reactions, apart from the reaction rate not only the intensity of mass exchange between fluid elements is important, but also the residence time of a molecule in the reactor.

In the case of maximum micromixing and constant density of the reacting system, the conversion is identical to that calculated for the CISTR. When segregated flow takes place, the situation is different. Each aggregate in the outlet stream can be considered as a batch reactor with a reaction time equal to its residence time. The fraction of aggregates having a residence time between t and $t + \Delta t$ is $E\,\Delta t$. If the remaining reactant concentration after conversion in a batch reactor with residence time t is $c_{\mathrm{A}}^{\mathrm{Batch}}(t)$, the average concentration at the outlet of the segregated continuous flow reactor CSSTR can be calculated:

$$\frac{\bar{c}_{\mathrm{A}}}{c_{\mathrm{A}_0}} = \frac{1}{c_{\mathrm{A}_0}} \int_0^\infty c_{\mathrm{A}}^{\mathrm{Batch}}(t)\, E \mathrm{d}t \tag{3.7}$$

or

$$\frac{\bar{c}_{\mathrm{A}}}{c_{\mathrm{A}_0}} = \frac{1}{c_{\mathrm{A}_0}} \int_0^\infty c_{\mathrm{A}}^{\mathrm{Batch}}(t)\, \frac{1}{\tau} \mathrm{e}^{-t/\tau} \mathrm{d}t \tag{3.8}$$

The average outlet concentrations for different reaction kinetic expressions for both ideal micromixing and segregated flow are listed in Table 3 [9]. Outlet concentrations are identical for both cases if a first-order reaction takes place.

Example [9]. Reactant A ($M_{\mathrm{A}} = 104$ kg/kmol) is to be polymerized in the dispersed phase in a continuous stirred-tank reactor. Based on batch-scale experiments, the following reaction rate expression was found:

$$R_{\mathrm{A}} = -k\, c_{\mathrm{A}}^{1.5}$$
$$\text{with } k = 2.5 \times 10^{-4}\, \mathrm{s}^{-1}\, \mathrm{kmol}^{-0.5}\, \mathrm{m}^{1.5}$$

The required size of the tank reactor shall be calculated for a production of 10 t/d of polymer with a relative degree of conversion $\bar{\zeta}_{\mathrm{A}} = 0.9$, under the assumption that coalescence between the liquid drops does not occur. The feed of the dispersed phase consists of pure A, and the density of this phase remains constant at a value of 832 kg/m^3 during the reaction. The volume fraction of the dispersed phase in the reactor is 0.165.

Solution. The average conversion $\bar{\zeta}_{\mathrm{A}}$ at the outlet of the CSSTR is obtained by rearrangement of Equation (3.8):

$$\bar{\zeta}_{\mathrm{A}} = \int_0^\infty \zeta_{\mathrm{A}}^{\mathrm{Batch}}(t)\, \frac{1}{\tau} \mathrm{e}^{-t/\tau} \mathrm{d}t \tag{3.8a}$$

Table 3. Design equations for ideally mixed CISTR and for completely segregated fluids CSSTR

Kinetics	CISTR
$R_A = -k c_A$	$\frac{c_A}{c_{A_0}} = \frac{1}{1+N_r}$
$N_r = k\tau$	
$R_A = -k$	$\frac{c_A}{c_{A_0}} = 1 - N_r,\ N_r \le 1;\ \frac{c_A}{c_{A_0}} = 0,\ N_r \ge 1$
$N_r = \frac{k\tau}{c_{A_0}}$	
$R_A = -k c_A^{0.5}$	$\frac{c_A}{c_{A_0}} = 1 - \frac{N_r^2}{2}\left[-1 + \sqrt{\left(1 + \frac{4}{N_r^2}\right)}\right]$
$N_r = \frac{k\tau}{\sqrt{c_{A_0}}}$	
$R_A = -k c_A^2$	$\frac{c_A}{c_{A_0}} = \frac{-1 + \sqrt{(1+4N_r)}}{2N_r}$
$N_r = k\tau c_{A_0}$	
$R_A = -k c_A^n$	$\left(\frac{c_A}{c_{A_0}}\right)^n N_r + \frac{c_A}{c_{A_0}} - 1 = 0$
$N_r = c_{A_0}^{n-1} k\tau$	

Kinetics	CSSTR
$R_A = -k c_A$	$\frac{\bar{c}_A}{c_{A_0}} = \frac{1}{1+N_r}$

$R_A = -k c_A^n$	$\frac{\bar{c}_A}{c_{A_0}} = \frac{1}{\tau}\int_0^\infty [1 + (n-1) c_{A_0}^{n-1} k t]^{\frac{1}{1-n}} e^{-t/\tau} dt$
$N_r = c_{A_0}^{n-1} k\tau$	

$^*\ Ei(-x) = \int_x^\infty \frac{e^{-y}}{y} dy$

The material balance for a batch system together with the rate expression yields:

$$\bar{\zeta}_A^{\text{Batch}} = 1 - \left(\frac{2}{2 + k t \sqrt{c_{A_0}}}\right)^2$$

By integrating Equation (3.8 a) a value of $k\tau \sqrt{c_{A_0}} = 15.4$ is found for $\bar{\zeta}_A = 0.9$. The calculated residence time τ is 6 h and the required volume of the dispersed liquid $\Phi_m \tau / 0.9\, \varrho_A$ is equal to $3.34\,m^3$. The total required volume in the reactor is $3.34\,m^3/0.165 = 20.2\,m^3$.

Start-Up of a CISTR. For non-steady-state operations, the accumulation term in Equation (3.1) cannot be neglected. Two different periods of non-steady-state operations in a CISTR can be distinguished:

1) Filling a reactor with reactants (variable reactor volume)
2) Non-steady-state operation at a constant reactor volume

In the case of an irreversible liquid reaction ($A \rightarrow B$) which takes place in a CISTR under isothermal and constant density conditions, the instant concentration in the reactor can be calculated as follows: For $t \le \tau$, no liquid leaves the reactor and the material balance leads to:

$$\frac{-d(c_A V)}{dt} = -\Phi_v c_{A_0} + k c_A V \tag{3.9}$$

in which the reaction volume is $V = \Phi_v t$. Integration of Equation (3.9) gives:

$$c_A = \frac{c_{A_0}}{kt}\left(1 - e^{-kt}\right) \quad \text{for } t \le \frac{V}{\Phi_v} \tag{3.10}$$

For $t > \tau$ the reaction volume V is constant and equals V_r and the product flow out of the reactor equals the feed rate Φ_v. The material balance for reactant A now becomes:

$$\begin{aligned}\frac{-d(c_A V_r)}{dt} &= -V_r \frac{dc_A}{dt} \\ &= -\Phi_v\left(c_{A_0} - c_A\right) + k c_A V_r\end{aligned} \tag{3.11}$$

Integration yields:

$$\frac{c_{A_0} - (1+k\tau)\, c_A}{c_{A_0} - (1+k\tau)\, c_{A_\tau}} = e^{-(1+k\tau)(t-\tau)/\tau} \quad \text{for } t > \tau \tag{3.12}$$

where $c_A = \frac{c_{A_0}}{k\tau}\left(1 - e^{-k\tau}\right)$

After a long time ($t \rightarrow \infty$) the right-hand side of Equation (3.12) approaches zero, so that ultimately the concentration c_A in the reactor reaches the value $c_{A\infty}$. A conservative estimate for the time required to reach steady state can be made by substituting $c_{A_\tau} = c_{A_0}$ in Equation (3.12) for the required degree of conversion.

3.2. Isothermal Heterogeneous Reactors

Contrary to reactions in a single phase where mixing takes place on a molecular scale, in a multiphase system not all reactive molecules present may be available for chemical reaction due to mass transfer limitations. For a reacting system consisting of two phases L and G, with a reaction taking place in phase L only, the mass balance equations are:

$$\frac{dm_{\mathrm{JL}}}{\mathrm{d}t} = -\Delta\left(\Phi_{\mathrm{mL}} w_{\mathrm{JL}}\right) + J_{\mathrm{JL}} M_{\mathrm{J}} a V_{\mathrm{r}} + R_{\mathrm{J}} M_{\mathrm{J}} (1-\varepsilon) V_{\mathrm{r}} \tag{3.13}$$

and:

$$\frac{dm_{\mathrm{JG}}}{\mathrm{d}t} = -\Delta\left(\Phi_{\mathrm{mG}} w_{\mathrm{JG}}\right) + J_{\mathrm{JG}} M_{\mathrm{J}} a V_{\mathrm{r}} \tag{3.14}$$

The term $R_{\mathrm{J}} M_{\mathrm{J}} (1-\varepsilon) V_{\mathrm{r}}$ is the production rate of J by a homogeneous chemical reaction in phase L where $(1-\varepsilon)$ is the volume fraction of the reaction phase per unit volume of a reactor. The terms $(-\Delta\Phi_{\mathrm{m}} w_{\mathrm{J}})$ and $(J_{\mathrm{J}} M_{\mathrm{J}} a)$ represent the net supply of component J by convection and the mass flow of J from the interface to the bulk of the phase, respectively.

When a reaction takes place in a system of two immiscible or partially miscible liquid phases, the overall process can be controlled by chemical reaction and/or mass transfer between both phases. In the case of a *chemically controlled process*, the overall rate expression in Equation (3.1) is the sum of the reaction rates in the individual phases.

When *mass transfer* is the rate-determining step, phase equilibrium cannot be achieved and the reaction rate is fast compared to the rate of mass transfer. Thus, the reaction proceeds as the reactants diffuse through the interface into the bulk of the other phase. If reactant A is a major component of phase I while phase II consists of reactant B and if equilibrium is attained at the interface, the rate of mass transfer of A from phase I to phase II would be equal to the rate of disappearance of A by chemical reaction in phase II. For an irreversible, second-order reaction between A and B, mass transfer of A from phase I to phase II can be described as:

$$J_{\mathrm{AII}} = k_{\mathrm{II}} a \left(\frac{c_{\mathrm{AI}}}{K_{\mathrm{A}}} - c^{0}_{\mathrm{AII}}\right)(V_{\mathrm{I}} + V_{\mathrm{II}}) \tag{3.15}$$

where k_{II} is the mass-transfer coefficient in phase II per unit volume of both phases (m/s), a is the interfacial area per unit volume of both phases ($\mathrm{m}^2/\mathrm{m}^3$), c_{AI} is the concentration of reactant A in phase I, K_{A} is the distribution coefficient of A between both phases, and c^{0}_{AII} is the steady-state concentration of A in phase II.

The value of the product of mass-transfer coefficient and interfacial area strongly depends on the reactor arrangement and empirical correlations must be used to scale-up such reacting systems [10], [11].

3.3. Nonisothermal Continuous Stirred-Tank Reactors

All chemical reactions are in principle accompanied by evolution or absorption of heat and these effects often have to be taken into account. For flow processes, the energy balance equation is

$$\frac{d\left(\langle u\rangle m\right)}{\mathrm{d}t} = -\Delta\left(h\Phi_{\mathrm{m}}\right) + \dot{Q} - \dot{W} \tag{3.16}$$

where h is the enthalpy per unit mass of the reaction mixture and $\langle u\rangle$ is the average internal energy over the reactor volume. For the steady-state operation of a continuous tank reactor provided with a heat exchange area A, the energy balance becomes:

$$\Phi_{\mathrm{m}}\left(h_1 - h_0\right) = UA\left(T_{\mathrm{c}} - T_1\right) \tag{3.17}$$

where the subscripts 1 and 0 refer to the conditions at the outlet and inlet, respectively; T_{c} is the temperature of the cooling or heating medium. The difference in enthalpy $(h_1 - h_0)$ can be calculated from:

$$h_1 - h_0 = \int_{T_{0,\mathrm{O}}}^{T_1 \xi_{\mathrm{J},1}} \left[c_p\,\mathrm{d}T + (\Delta h_{\mathrm{r}})_{\mathrm{J}}\,\mathrm{d}\xi_{\mathrm{J}}\right] \tag{3.18}$$

where c_p is the specific heat capacity at constant pressure and (Δh_{r}) the enthalpy of reaction at constant pressure per unit mass of J converted. If the density and heat capacity of the system are constant, the energy balance for reactant A gives:

$$-(\Delta H_{\mathrm{r}})_{\mathrm{A}}\left(c_{\mathrm{A}_0} - c_{\mathrm{A}_1}\right) = c_p \varrho\left(T_1 - T_0\right) + \frac{UA}{\Phi_v}\left(T_1 - T_{\mathrm{c}}\right) \tag{3.19}$$

where $(\Delta H_r)_A$ is the heat of reaction per mole of A converted. In the case of a first-order irreversible reaction Equations (3.1) and (3.19) can be rewritten to:

$$-(\Delta H_r)_A\, c_{A_0} \frac{k\tau}{1+k\tau} = \varrho c_p (T_1 - T_0) + \frac{UA}{\Phi_v}(T_1 - T_c) \tag{3.20}$$

In order to find the maximum temperature T_1, Equation (3.20) must be solved by trial and error, either numerically or graphically, because k is an exponential function of temperature. The left-hand side of Equation (3.20) represents the heat produced per unit volume of a reaction mixture. The right-hand side represents the heat removed per unit volume of the reaction mixture as a result of the heat absorbed by the cold feed and the heat transferred to the cooling medium. The maximum temperature rise can be reached when the system is adiabatic (no heat transfer to the surroundings) and complete conversion is achieved:

$$\Delta T_{ad} = \frac{-(\Delta H_r)_A\, c_{A_0}}{\varrho c_p} \tag{3.21}$$

Autothermal Reactor Operation. The heat released during an exothermic reaction is often used for preheating inlet reactant streams. A reactor system, in which such a feedback of reaction heat to the incoming reactant stream takes place is said to operate under autothermal conditions. The theory of steady-state behavior of autothermal reactors is described in [12], [13].

Multiplicity (→ Principles of Chemical Reaction Engineering, Chap. 7.2.2.). In Figure 8 both right- (heat removal) and left-hand sides (heat production) are plotted for different inlet and operating conditions. At the intersection of the heat production (solid line) and heat removal curves (dashed lines), Equation (3.20) is obeyed. For a certain range of inlet parameters several solutions may exist (multiplicity of steady states). If the heat removal is represented by line 1 in Figure 8, the reactor is cooled so effectively that steady-state operation is possible only at a low temperature and a very low degree of conversion. If the cooling rate is lowered (line 2), three points of intersection occur with the heat generation curve. The two intersection points, the lowest and highest reaction temperature, represent stable conditions due to the fact that the rate of heat removal is higher than that generated in the system. The intermediate intersection point is unstable. Since the slope of the heat production curve at the intermediate point is greater than that of the heat removal line, any positive temperature perturbation will be amplified until the reactor reaches the upper stable operating point, and negative temperature deviation leads to extinction (lower stable operating point). If the feed temperature T_0 and the cooling capacity are such that the heat removal line 3 prevails (see Fig. 8), the reactor operates in an upper stable state and no special measures need be taken to start up a process.

Figure 8. Heat production (—) and heat removal (– – –) in a nonisothermal CISTR for an irreversible exothermic reaction A → R

Figure 9. Regions of multiplicity in a CISTR [5]
T = Trifurcation point; —— $\tau = 1$ s; – – – $\tau = 0.5$ s

In Figure 9 a multiplicity region is presented as a function of the maximum temperature increase in the reactor, $\left(\frac{\Delta T_{\mathrm{ad}}}{1+St'}\right)$. In the area enveloped by the curves multiplicity will occur. Outside, only one (stable) operating point is possible. Operating points located above the multiplicity region are distinguished by a high degree of conversion, those below the multiplicity region by a low degree of conversion. The point with the lowest value of $\frac{\Delta T_{\mathrm{ad}}}{1+St'}$ where multiplicity occurs is often called the *trifurcation point*, and the curves departing from it, the *bifurcation lines*.

HLAVACEK et al. derived the criteria for existence of multiplicity of steady states for first-order reactions [14]. Multiplicity occurs when the dimensionless adiabatic temperature rise $B = \frac{(-\Delta H_{\mathrm{r}})\, c_{\mathrm{A}_0}}{\varrho c_p T_0} \frac{E}{RT_0}$ exceeds a critical value of$B*$:

1) Adiabatic case ($\bar{\beta} = 0$)

$$B^* = \frac{4\bar{\gamma}}{\bar{\gamma}-4}$$

2) Adiabatic case ($\bar{\beta} = 0$); $\bar{\gamma} \to \infty$

$$B^* = 4$$

3) Nonadiabatic case; $\bar{\gamma} \to \infty$

$$B^* = 4\bar{\delta}$$

4) Nonadiabatic case

$$B^* = \frac{4\left(\bar{\varepsilon}+\bar{\delta}\bar{\gamma}\right)^2}{\bar{\gamma}\bar{\delta}\left(\bar{\gamma}-4\right)-4\bar{\varepsilon}}$$

where $\bar{\gamma} = E/RT_0$ is a dimensionless activation energy, $\bar{\beta} = UA/\Phi_v\, \varrho\, c_p$ is a dimensionless heattransfer coefficient, $\bar{\delta} = 1 + \bar{\beta}$, $\bar{\varepsilon} = \bar{\beta}\,\bar{\Theta}_{\mathrm{c}}$, and $\Theta_{\mathrm{c}} = \frac{E}{RT_0^2}\left(T_{\mathrm{c}} - T_0\right)$ is a dimensionless cooling temperature.

Hysteresis in Autothermal Systems (→ Principles of Chemical Reaction Engineering).

If the feed temperature T_0 is increased at a constant feed rate, the reaction will be ignited at a certain feed temperature $(T_0)_{\mathrm{ign}}$ and the reactor will operate at the upper stable steady state. If T_0 is then lowered again, the reactor continues operating at a high conversion level until extinction takes place at a feed temperature $(T_0)_{\mathrm{ext}}$.

Stability of Autothermal CISTR. The transient behavior of strongly exothermic reacting systems may lead to unexpected, undesired changes in a reactor. This is a result of coupling between the material and energy balances (Eqs. 3.1 and 3.16). Detailed information on dynamic behavior of autothermal systems can be found in [15–17].

The mass and energy balance equations Equations (3.1) and (3.16) can be rewritten to:

$$\frac{d\zeta}{\mathrm{d}\Theta} = -\zeta + \frac{\tau R_{\mathrm{A}}}{c_{\mathrm{A}_0}} \tag{3.22}$$

and:

$$\frac{dT}{\mathrm{d}\Theta} = T_0 - T - \Delta T_{\mathrm{ad}} \frac{R_{\mathrm{A}}\tau}{c_{\mathrm{A}_0}} + St'\left(T_{\mathrm{c}} - T\right) \tag{3.23}$$

where $\tau = \varrho\, V_{\mathrm{r}}/\Phi_{\mathrm{m}}$ is the average residence time, $\Theta = t/\tau$ is a dimensionless time, and St' a modified Stanton number ($St' = UA/c_p\, \Phi_v$).

In the case of a first-order reaction Equations (3.22) and (3.23) can be rewritten to:

$$\frac{d\zeta}{\mathrm{d}\Theta} = -\zeta + k_{\mathrm{s}}\tau\left(1-\zeta\right)\mathrm{e}^{\Delta\vartheta} \tag{3.24}$$

$$\frac{d\vartheta}{\mathrm{d}\Theta} = -\left(1+St'\right)\Delta\vartheta + \Delta\vartheta_{\mathrm{ad}} k_{\mathrm{s}}\tau\left(1-\zeta\right)\mathrm{e}^{\Delta\vartheta} + \Delta\vartheta_0 + St'\,\Delta\vartheta_{\mathrm{c}} \tag{3.25}$$

where:

$$\Delta\vartheta_0 = \left(T_0 - T_{\mathrm{s}}\right)\frac{E}{RT_{\mathrm{s}}^2}$$

$$\Delta\vartheta_{\mathrm{c}} = \left(T_{\mathrm{c}} - T_{\mathrm{s}}\right)\frac{E}{RT_{\mathrm{s}}^2}$$

$$\Delta\vartheta_{\mathrm{ad}} = \Delta T_{\mathrm{ad}}\frac{E}{RT_{\mathrm{s}}^2}$$

and k_{s} is the reaction rate constant at temperature T_{s}.

When a small perturbation is imposed on a steady state, Equations (3.24) and (3.25) can be linearized as follows:

$$\frac{d\Delta\zeta}{\mathrm{d}\Theta} = -\frac{1}{1-\zeta_{\mathrm{s}}}\Delta\zeta + \zeta_{\mathrm{s}}\Delta\vartheta \equiv a_{11}\Delta\zeta + a_{12}\Delta\vartheta \tag{3.26}$$

and:

$$\frac{d\Delta\vartheta}{\mathrm{d}\Theta} = \frac{\Delta\vartheta_{\mathrm{ad}}\zeta_{\mathrm{s}}}{1-\zeta_{\mathrm{s}}}\Delta\zeta + \left[\Delta\vartheta_{\mathrm{ad}}\zeta_{\mathrm{s}} - \left(1+St'\right)\right]\Delta\vartheta \equiv a_{21}\Delta\zeta + a_{22}\Delta\vartheta \tag{3.27}$$

where $\Delta\zeta = \zeta - \zeta_s$ and $\Delta\vartheta = \vartheta - \vartheta_s$; ζ_s and ϑ_s are the conversion and the dimensionless temperature at steady state.

The solution of Equation (3.26) and (3.27) has the form:

$$\Delta\zeta = b_{11}e^{p_1\Theta} + b_{12}e^{p_2\Theta} \tag{3.28}$$

$$\Delta\vartheta = b_{21}e^{p_1\Theta} + b_{22}e^{p_2\Theta} \tag{3.29}$$

where:

$$p_{1,2} = \frac{(a_{11}+a_{22})}{2}\left[1 \pm \sqrt{\left(1 - \frac{4\,(a_{11}a_{22} - a_{12}a_{21})}{(a_{11}+a_{22})^2}\right)}\right]$$

The chemical process is stable when:

$$\frac{1 + St'}{\Delta\vartheta_{ad}} > \zeta_s\,(1 - \zeta_s) \tag{3.30}$$

and:

$$\frac{1}{1 - \zeta_s} - \Delta\vartheta_{ad}\,\zeta_s + 1 + St' > 0 \tag{3.31}$$

where $\zeta_s = k\,\tau/(1 + k\,\tau)$ in the case of first-order reaction.

If the second condition (Eq. 3.31) is met, the reactor is dynamically stable and operates at its steady state (ζ_s, T_s). However, if this condition is not satisfied the reactor is dynamically unstable and operates in a fixed *limit cycle* around the steady-state point (ζ_s, T_s) (Fig. 10).

Figure 10. The limit cycle in CSTR [18]

3.4. Cascade of Tank Reactors [21]

Continuous stirred-tank reactors in series (Fig. 11) are used when the required residence time is long and more than one vessel is necessary for efficient, economical mixing. Conversions, yields, and residence times of the individual stirred-tank reactors are calculated analogously to those for a single CISTR. The steady-state *material balance* over the *n*th reactor for a component J reads:

$$\xi_{Jn} - \xi_{J\,(n-1)} = \frac{V_{rn}}{\Phi_m} M_J\, R_{Jn} \tag{3.32}$$

In most cases, the set of equations describing the degree of conversion in a cascade cannot be solved analytically. For a system consisting of *n* equal-sized CISTRs in series an analytical solution can be obtained for first-order irreversible reactions [19]:

$$c_{An} = c_{A_0}\,(1 + k\tau)^{-n} \tag{3.33}$$

and for second-order reaction: $c_{An} = 14\,k\,\tau_i$

$$c_{An} = \frac{1}{4k\tau_i}\left(-2 + 2\cdot\sqrt{-1\ldots + \sqrt{-1 + 2\sqrt{1 + 4k\,c_{A_0}\tau_i}}}\cdot s^n\right) \tag{3.34}$$

In other cases a solution has to be found by an algebraic stepwise method or by a graphical technique [9], [20].

Example. The second-order, reversible reaction $2\,A \rightleftharpoons C + D$ is carried out in a single CISTR with total volume of 2.665 m^3. The volumetric flow rate of reactant A is 7.866×10^{-4} m^3/s, and its inlet and outlet concentrations are 24.03 and 6.94 $kmol/m^3$, respectively. The forward rate constant at the reaction temperature is 1.156×10^{-4} $m^3\,kmol^{-1}\,s^{-1}$ and the equilibrium constant *K* is 16.0.

It now becomes necessary to replace the working reactor with a series of identical CISTRs. The volume of each reactor in a new reactor arrangement should be one-tenth of the current one. How many CISTRs are required?

Figure 11. Continuous stirred-tank reactors in series (cascade)

Solution. The reaction rate can be expressed as follows:

$$R_{\mathrm{A}} = k_1 \left[c_{\mathrm{A}}^2 - \frac{\left(c_{\mathrm{A}_0} - c_{\mathrm{A}}\right)^2}{4K} \right]$$

The relation between R_{A} and c_{A} described by the above equation is shown in Figure 12. In addition, the balance equation

$$R_{\mathrm{A}} = \frac{\Phi_v}{V_{\mathrm{r}}} \left[c_{\mathrm{A}n} - c_{\mathrm{A}(n-1)} \right]$$

is also valid for each reactor in a series. The slope Φ_v / V_{r} in the case of a new arrangement is $2.95 \times 10^{-3}\,\mathrm{s}^{-1}$. A straight line through $c_{\mathrm{A}_0} = 24.03\,\mathrm{kmol/m^3}$ with this slope can be drawn to the intersection with the reaction rate curve. This process has to be repeated until $c_{\mathrm{A}n} = 6.94\,\mathrm{kmol/mol}$ is reached. From Figure 12, the number of stages required is 3.8. Hence four CSTRs should be used in this case.

Figure 12. Graphical estimation of required number of CSTRs in series

Figure 13. Different configurations for packed-bed reactors A) Multitube heat exchanger; B) Multistage adiabatic reactor
According to "Chemical Reactor Analysis and Design" G. F. Froment, K. B. Bischoff, John Wiley & Sons, New York 1990.

4. Packed-Bed Reactors

The packed-bed reactor constitutes the keystone in the production of several important chemicals. Several reactor configurations are encountered in practice (e.g., Fig. 13). The *heat-exchanger type* of reactor (Fig. 13 A) is used to carry out highly exothermic reactions. The *adiabatic multistage reactor* (Fig. 13 B) with cooling between stages is used to carry out exothermic equilibrium reactions. The *autothermal configuration*, an interesting alternative, is a heat-exchanger type of reactor in which the reactants circulate alternatively through shell and tube arrangements with the double purpose of being preheated and keeping the reactor operating within a prespecified thermal regime by cooling it down.

The analysis of transport phenomena for systems with chemical reaction is usually based on the transport equations resulting from the differential balance laws. To predict global effects, detailed information about the velocity profiles, and temperature and concentration fields is required. This information is extracted from the solution of the associated transport equations, subject to pertinent boundary conditions. When flow through a complex structure such as a porous medium is involved, these governing equations are valid even inside the pores. However, the geometric complexity of a randomly ordered particulate system prevents any general solution of detailed concentration, temperature, and flow fields. Instead, some form of macroscopic balances based on the average over a small volumetric element must be employed. A common practice is, with the help of some empirical relations, to replace the microscopic momentum, mass, and energy balances with corresponding macroscopic equations.

Due to the distributed nature of the system, a dynamic model contains two or more independent variables (time and spatial coordinates). Simultaneously, it is important in principle to include all relevant transport resistance (see Fig. 14) to avoid unrealistic results. Since a very complex model may be too difficult to solve, a number of simplifying assumptions are often adopted in practice. However, care must be taken when choosing the adequate degree of complexity for the reactor model, so as to guarantee sufficient accuracy for a given practical application.

Figure 14. Energy transport mechanisms in packed beds

4.1. Mass and Energy Balances

Mathematical models for adiabatic and nonadiabatic packed-bed reactors have been systematically listed in reviews by Froment [22], Hlavacek [23], and Hofmann [24]. In these reviews an attempt is made to classify the models according to their complexity. Basically, the mathematical modeling of fixed-bed reactors can be performed either through the finite-stage or the continuum approach [25]. The continuum approach leads to a system of partial differential equations in which mixing effects are accounted for in the form of mass diffusion and heat conduction terms. This approach is being increasingly favored, mainly due to the continuous progress in computer software and numerical modeling.

In general, for the mathematical treatment of the heat and mass transfer processes in packed beds, with or without chemical reaction, three types of continuous models have been developed:

1) The single-particle model, where intra particle phenomena are accounted for separately
2) The two-phase (heterogeneous) model in which both phases, solid and fluid, exchange heat and/or mass, and such transport processes are accounted for
3) The one-phase (pseudohomogeneous) model in which the reactor is approximated as a quasi- continuum model

4.1.1. The Single-Particle Model

Basically the single-particle model is also a heterogeneous model. However, it differs from the two-phase model in that the solid phase is not regarded as a continuum since the concentration and temperature distribution inside the single pellet are accounted for.

Consider a catalyst pellet positioned in a flowing stream (Fig. 15). Three different regions can be distinguished: the bulk fluid phase, the boundary layer surrounding the particle, and the particle itself.

Figure 15. Schematic of a single particle in a flowing stream

Bulk Fluid Phase. The bulk fluid phase can be modeled as a constant temperature and constant concentration field. Perturbations at the inlet of the reactor propagate through the fluid and the conditions at the outer edge of the boundary layer change accordingly; this dynamic evolution of the boundary condition can be solved by using a heterogeneous model (see Section 4.1.2).

Boundary Layer. Temperature and concentration conditions in the boundary layer are frequently assumed to be identical to those of the bulk fluid phase. This is not always the case and, particularly if it is desired to trace the dynamic behavior of the concentration and temperature fields inside the catalyst pellets, the temperature and concentration in the boundary layer must be obtained by solving the corresponding mass and energy balances. The first step in solving these fields is to determine the extent of the boundary layer. This can be accomplished by performing overall energy and mass balances across the boundary layer. Once the thickness of the boundary layer has been found (e.g., Δr), the governing equations and their boundary conditions will be defined by:

Mass balance:

$$\frac{\partial C_{\mathrm{f}}}{\partial t} = D_{\mathrm{f}} \nabla^2 C_{\mathrm{f}} \tag{4.1}$$

Energy balance:

$$\varrho_{\mathrm{g}} C_{p,\mathrm{f}} \frac{\partial T_{\mathrm{f}}}{\partial t} = \lambda_{\mathrm{f}} \nabla^2 T_{\mathrm{f}} \tag{4.2}$$

subject to:

$$\left.\begin{aligned} C_{\mathrm{f}} &= C_{\mathrm{f}}(t) \\ T_{\mathrm{f}} &= T_{\mathrm{f}}(t) \end{aligned}\right\} \text{ at } r = R + \Delta r \tag{4.3}$$

$$\left.\begin{aligned} &\frac{\partial C_{\mathrm{f}}}{\partial r} = -\eta R(C_{\mathrm{s}}, T_{\mathrm{s}}) \\ &\lambda_{\mathrm{s}} \left.\frac{\partial T_{\mathrm{s}}}{\partial r}\right|_{r \to R^-} - \lambda_f \left.\frac{\partial T_f}{\partial r}\right|_{r \to R^+} \\ &= \eta(-\Delta H_r) R(C_{\mathrm{s}}, T_{\mathrm{s}}) \end{aligned}\right\} \text{ at } r = R \tag{4.4}$$

where η is the effectiveness factor, the subscript f denotes fluid, and $R(C_{\mathrm{s}}, T_{\mathrm{s}}) = k_0^* C_{\mathrm{s}} \exp(-E_{\mathrm{a}}/RT)$ stands for the equation for the reaction rate [26].

Catalyst Pellet. Similar to the analysis of the boundary layer, the pellet itself is modeled in terms of mass and energy transport. The pellet can be either porous or nonporous; in the latter case there is no mass diffusion of species into the pellet and only an energy balance is necessary. For certain classes of reactions, the assumption of nonporous catalyst is justifiable, e.g., for reactions whose high exothermicity prevents the reaction front from penetrating deep into the pellet even if it were porous. Under these assumptions the energy balance for the catalyst pellet gives:

$$\varrho_{\mathrm{s}} C_{p,\mathrm{s}} \frac{\partial T_{\mathrm{s}}}{\partial t} = \lambda_{\mathrm{s}} \nabla^2 T_{\mathrm{s}} \tag{4.5}$$

subject to:

$$\frac{\partial T_{\mathrm{s}}}{\partial \tau} = 0 \quad \text{at} \quad r = 0$$

$$k_{\mathrm{s}} \frac{\partial T_{\mathrm{s}}}{\partial r}\Big|_{\mathrm{r}\to R^-} - \lambda_f \frac{\partial T_f}{\partial r}\Big|_{r\to R^+} = \eta\left(-\Delta H_r\right) R\left(C_{\mathrm{s}}, T_{\mathrm{s}}\right) \text{ at } r = R \tag{4.6}$$

4.1.2. The Two-Phase Model

Of the two remaining models, the two-phase model is not only more realistic but it also constitutes the basis on which the derivation of the pseudohomogeneous approximation relies.

The most important feature of this model is that temperature and concentration differences are considered between solid and fluid phases. The mass and energy transport processes are governed by the following equations:

Fluid phase:

$$\varepsilon \frac{\partial\left(C_{\mathrm{i,f}}\right)}{\partial t} = -\varepsilon \nabla \cdot \left(\boldsymbol{u} C_{\mathrm{i,f}}\right) + \varepsilon \nabla \cdot \mathbf{D}_{\mathrm{f}} \cdot \nabla C_{\mathrm{i,f}} + a_v \lambda_{\mathrm{f,s}}\left(C_{\mathrm{i,s}} - C_{\mathrm{i,f}}\right) \tag{4.7}$$

$$\varepsilon \varrho_{\mathrm{f}} C_{\mathrm{p,f}} \frac{\partial T_{\mathrm{f}}}{\partial t} = -\varepsilon \varrho_{\mathrm{f}} C_{p,\mathrm{f}} \boldsymbol{u} \cdot \nabla T_{\mathrm{f}} + \varepsilon \nabla \cdot \lambda_{\mathrm{f}} \cdot \nabla T_{\mathrm{f}} + a_v h_{\mathrm{f,s}}\left(T_{\mathrm{s}} - T_{\mathrm{f}}\right) \tag{4.8}$$

Solid phase:

$$(1-\varepsilon)\, \varepsilon_{\mathrm{p}} \frac{\partial\left(C_{\mathrm{i,s}}\right)}{\partial t} = -\eta\,(1-\varepsilon)\, \varrho_{\mathrm{s}} R\left(C_{1,\mathrm{s}}, \ldots, C_{\mathrm{i,s}}, \ldots, C_{\mathrm{S,s}}, T_{\mathrm{s}}\right) + a_v\, \lambda_{\mathrm{f,s}}\left(C_{\mathrm{i,f}} - C_{\mathrm{i,s}}\right) \tag{4.9}$$

$$(1-\varepsilon)\, \varrho_{\mathrm{s}} C_{p,\mathrm{s}} \frac{\partial T_{\mathrm{s}}}{\partial t} = \eta\,(1-\varepsilon)\, \varrho_{\mathrm{s}}\left(-\Delta H_r\right) R\left(C_{1,\mathrm{s}}, \ldots, C_{\mathrm{i,s}}, \ldots, C_{\mathrm{S,s}}, T_{\mathrm{s}}\right) + (1-\varepsilon)\, \boldsymbol{\nabla} \cdot \lambda_{\mathrm{s}} \cdot \boldsymbol{\nabla} T_{\mathrm{s}} + a_v\, h_{\mathrm{f,s}}\left(T_{\mathrm{f}} - T_{\mathrm{s}}\right) \tag{4.10}$$

4.1.3. The One-Phase Model

By introduction of the effective transport concept heterogeneous fluid – solid systems can be treated as quasi- continuum media [27]. In the pseudohomogeneous model, additional transfer mechanisms are superimposed on the contributions that originate from the global movement of the fluid. These additional mechanisms are based upon the observation that the fluid traveling between two points of the packed bed undergoes a tortuous journey that is composed of a large number of random steps. It is assumed that the transfer mechanisms resulting from this process can be treated as diffusion- and conduction-like phenomena. The fact that the modeled system is actually heterogeneous is accounted for by defining transport coefficients where both contributions due to the solid and fluid phases are considered.

Although the two-phase models fulfill the obvious physical requirements of considering a system where two phases exchange mass and/or energy, they also contain a number of approximations. For instance, separation of thermal dispersion effects, which in fact are interconnected, is very difficult. An even more difficult problem arises when heat losses must be accounted for; in this case the wall heat transfer coefficient has to be resolved into its solid- and fluid-phase components. Ramkrishna and Arce discussed the validity of the pseudohomogeneous model to represent the heterogeneous nature of packed-beds [28], [29].

The simplest, most obvious pseudohomogeneous model was derived by Yagi et al. [30]. These authors made use of the fact that, at low Reynolds number, temperature differences between the solid and fluid phases are negligible and both phases can be assumed to have the same temperature. This approach has been generalized, and the one-phase model is adopted, even for high Reynolds number, based on the assumption of equal temperatures in both phases (e.g., [31]).

The idea of equivalence was extended by Vortmeyer et al. [32], [33] for arbitrary Reynolds numbers. These authors combined the energy balances for the fluid and solid phases (Eqs. 4.8 and 4.10) by assuming that the driving forces for heat conduction were similar in both phases. The main difference to the approach followed by Yagi and coworkers is that Vortmeyer and coworkers derived a dispersion term which reflects the exchange of energy between both phases; this term is added to the thermal

conductivity of the solid phase to form a quantity which is known as the effective thermal conductivity.

An additional assumption concerns the mass transport between the solid and fluid phases. The resistance to mass transfer of the film adjacent to the solid particles can often be considered negligible; thus, the surface reactant concentration can be considered similar to that in the bulk of the fluid phase.

Under these assumptions and by combining both energy balances (Eqs. 4.8 and 4.10), the transport processes in the packed-bed reactor can be considered as governed by the following set of equations:

Mass balance:

$$\varepsilon \frac{\partial (C_\mathrm{i})}{\partial t} = -\varepsilon \boldsymbol{\nabla} \cdot (\boldsymbol{u} C_\mathrm{i}) + \varepsilon \boldsymbol{\nabla} \cdot \boldsymbol{D}_\mathrm{e} \cdot \boldsymbol{\nabla} C_\mathrm{i} - \eta (1-\varepsilon)\, \varrho_\mathrm{s} R\, (C_1, \ldots, C_\mathrm{i}, \ldots, C_\mathrm{S}, T) \tag{4.11}$$

Energy balance:

$$\overline{\varrho C_p} \frac{\partial T}{\partial t} = -\varepsilon\, \varrho_\mathrm{f} C_{p,\mathrm{f}}\, \boldsymbol{u} \cdot \boldsymbol{\nabla} T + \boldsymbol{\nabla} \cdot \lambda_\mathrm{e} \cdot \boldsymbol{\nabla} T + \eta (1-e)\, \varrho_\mathrm{s} (-\Delta H_r)\, R\, (C_1, \ldots, C_\mathrm{i}, \ldots, C_\mathrm{S}, T) \tag{4.12}$$

where:

$$\overline{\varrho C_\mathrm{p}} = \varepsilon \varrho_\mathrm{f} C_{p,\mathrm{f}} + (1-\varepsilon)\, \varrho_\mathrm{s} C_{p,\mathrm{s}}$$

An alternative two-phase model was proposed by CARBERRY and WHITE [34]. This model combines the pseudohomogeneous and heterogeneous models; it is based on the catalyst particle but uses effective transport properties. As a hybrid between the two previous models it has been termed the "pseudoheterogeneous" model. By considering the solid phase to be discontinuous, this model appears to perform better when matching models. A thorough analysis of this model is given in [35].

4.1.4. Boundary Conditions

Since the classical works by HULBURT [36], DANCKWERTS [37], and WEHNER and WILHELM [38] appeared, boundary conditions in packed-bed reactors have received much attention. The formulation of the boundary conditions proposed by DANCKWERTS is the most often followed. This formulation meets the limiting mixing conditions of the continuous stirred-tank reactor (CSTR) and the plug-flow reactor (PFR). This was proven for isothermal [39] and nonisothermal [40] systems. These boundary conditions have also been shown to be adequate for systems with a multiplicity of steady states [41]. They also predict the behavior of nonadiabatic systems satisfactorily [42] even though the number of possible steady states in these systems could change if the WEHNER and WILHELM approach is followed [43].

Even though the formulation of the boundary conditions as suggested by WEHNER and WILHELM [38] appears more logical from a physical point of view, their correspondence with DANCKWERTS' suggestion for steady-state operation of adiabatic systems has been proven [44]. Modifications have been proposed when radial dispersion is also taken into account [45], and the boundary conditions have also been modified to treat the transient situation [46], [47].

For selection of the proper boundary and initial conditions for flow systems see [48][49][50]. A simple pseudohomogeneous model without radial dispersion is now considered. The reactor is visualized as a tube with three distinguishable sections (see Fig. 16): the reaction zone packed with the catalyst ($0 \le z \le L$), and a fore ($z < 0$) and aft ($z > L$) sections of inert packing. A general formulation of the inlet and exit boundary conditions can be written as:

Inlet ($z = 0$):

$$\left[D_{\mathrm{e},z} \frac{\partial C_\mathrm{i}}{\partial z} - u_z C_\mathrm{i} \right]_{0-} = \left[D_{\mathrm{e},z} \frac{\partial C_\mathrm{i}}{\partial z} - u_z C_\mathrm{i} \right]_{0+} \tag{4.13}$$

$$\left[\lambda_{\mathrm{e},z} \frac{\partial T}{\partial z} - u_z\, \varrho_\mathrm{f} C_{p,\mathrm{f}} T \right]_{0-} = \left[\lambda_{\mathrm{e},z} \frac{\partial T}{\partial z} - u_z\, \varrho_\mathrm{f} C_{p,\mathrm{f}} T \right]_{0+} \tag{4.14}$$

Exit ($z = L$):

$$\left[D_{\mathrm{e},z} \frac{\partial C_\mathrm{i}}{\partial z} \right]_{L-} = \left[D_{\mathrm{e},z} \frac{\partial C_\mathrm{i}}{\partial z} \right]_{L+} \tag{4.15}$$

$$\left[\lambda_{\mathrm{e},z} \frac{\partial T}{\partial z} \right]_{L-} = \left[\lambda_{\mathrm{e},z} \frac{\partial T}{\partial z} \right]_{L+} \tag{4.16}$$

where a given approach is followed by selecting the diffusivities/conductivities as indicated in Table 4 ("yes" means parameter is included in the model, "no" means not included).

Table 4. Dispersion coefficients for different boundary conditions

Parameter	Hulburt	Danckwerts	Wehner and Wilhelm
$D/\lambda_{e,z}$ — $_{0-}$	no	no	yes
$D/\lambda_{e,z}$ — $_{0+}$	no	yes	yes
$D/\lambda_{e,z}$ — $_{L-}$	yes	yes	yes
$D/\lambda_{e,z}$ — $_{L+}$	no	no	yes

The conditions for the mass balance at the lateral walls are such that it is assumed that no mass flux occurs because the lateral walls are often impermeable (radial reactors are an exception). The boundary conditions for the energy balance, however, vary depending on whether the reactor is operated adiabatically or nonadiabatically. For a pseudohomogeneous model with radial dispersion these boundary conditions are:

Reactor wall (r=R):

$$\frac{\partial C_i}{\partial r} = 0 \tag{4.17}$$

$$\lambda_{e,r}\frac{\partial T}{\partial r} = h_w\,(T_w - T) \tag{4.18}$$

Reactor centerline (r=0):

$$\frac{\partial C_i}{\partial r} = 0 \tag{4.19}$$

$$\frac{\partial T}{\partial r} = 0 \tag{4.20}$$

4.2. Values of the Parameters

Various steps have been taken towards the derivation of an integral model for the packed-bed reactor by considering the individual steps involved in the transport of a given property in a packed bed. In this section only few correlations for typical applications will be mentioned, for more details, see [25], [51][52–54].

4.2.1. Average Bed Porosity

The existence of oscillatory radial variations of the void fraction in packed beds has been recognized since the early work of Roblee et al. [55] and Benenati and Brosilow [56], [57]. This nonuniform distribution of the porosity causes the flow to be nonuniformly distributed, particularly near the reactor walls [58], [59]. The inclusion of radial porosity and velocity profiles improves the agreement between experimental and theoretical results [60], [61]. It has been found [62], however, that the predictions obtained by assuming constant average porosity and main-flow velocity for the entire packed bed will be qualitatively correct in most cases.

$$\left[D_{e,z}\frac{\partial C_i}{\partial z} - u_z C_i\right]_{0^-} = \left[D_{e,z}\frac{\partial C_i}{\partial z} - u_z C_i\right]_{0^+} \tag{4.13}$$

$$\left[\lambda_{e,z}\frac{\partial T}{\partial z} - u_z \varrho_f C_{p,f} T\right]_{0^-} = \left[\lambda_{e,z}\frac{\partial T}{\partial z} - u_z \varrho_f C_{p,f} T\right]_{0^+} \tag{4.14}$$

Figure 16. Schematic of the flow system in a packed-bed reactor

In order to use a constant average porosity, the following integral relation must be fulfilled:

$$\varepsilon = \frac{1}{\pi R^2}\int_0^R \varepsilon(r)\, r\,\mathrm{d}r$$

There is no unique functional relation between the radius and the porosity, but many functionalities have been proposed in the literature. To find a realistic value for the average porosity, the approach suggested by Martin can be followed [63]. The bed is considered to be formed by two concentric rings with their own properties; a central core with an average porosity ε_0 and a one-particle-diameter-thick concentric shell with porosity ε_w. The average porosity, as defined above, must satisfy the relation:

$$\varepsilon_0 A_0 + \varepsilon_w A_w = \varepsilon A$$

Then, from geometric considerations, the following equation results:

$$\varepsilon = \varepsilon_w - (\varepsilon_w - \varepsilon_0)(1 - d/D)^2$$

where the porosity for the outer shell (ε_w) is estimated as [63]:

$$\varepsilon_w = 1 - (1 - \varepsilon_{min}) \frac{2}{3} \left(\frac{D/d - 7/8}{D/d - 1/2} \right)$$

where ε_{min} is the minimum value observed for the void fraction ($\varepsilon_{min} = 0.23$ and $\varepsilon_0 = 0.39$ are taken from [56]).

4.2.2. Effective Transport Coefficients

Since the effective transport coefficients are mainly determined by the flow characteristics, in general, packed beds are anisotropic for effective transport, so that the radial transport component is different from its analogue in the axial direction. For the sake of simplicity, effective transport coefficients are often considered to be unaffected by secondary flow and dependent on the mainflow (forced) only.

Mass Transport. A correlation for the mass transport in both spatial directions is [64]:

$$D_{e(r,z)} = \langle u \rangle_z d \times \left[\frac{0.7}{ReSc} + \frac{C_1}{1 + \left(\frac{C_2}{ReSc} \right)} \right]$$

where the constants C_1 and C_2 depend on the geometry of the packing and the fluid flowing through the packed bed as listed in Table 5.

Table 5. Constants for the effective mass-transport coefficients [64]

Constant	Liquids		Gases	
	Spherical packing	Irregular packing	Spherical packing	Irregular packing
C_1 (longitudinal)	2.5	2.5	0.7	4
C_1 (radial)	0.08	0.08	0.12	0.12
C_2 (longitudinal)	8.8	7.7	5.8	5.1
C_2 (radial)			78 ± 20	

A more heuristic approach is to assume a constant value for the axial and radial Bodenstein (or mass Péclet) numbers, i.e.,

$$Pe_{m,z/r} = \frac{\langle u \rangle_z d}{D_{e,z/r}} = \text{constant}$$

where z/r denotes that the expression is valid for both axial and radial transport.

Experimental evidence has shown that *axial dispersion* in packed beds is typically characterized by $Pe_{m,z} \approx 2$. In other words, CSTR conditions (small $Pe_{m,z}$) are reached in the void within each void cell, and the packed-bed reactor can be viewed as (L/d) CSTRs in series [65]. Therefore, axial mass diffusion can be neglected for ratios $L/d > 50$. This criterion applies to systems with particle Reynolds number larger than unity (i.e., $Re_p = \varrho_f \langle u \rangle_z d/\mu_f > 1$).

Radial mass dispersion is characterized by a constant radial mass Péclet number:

$$Pe_{m,r} = \frac{\langle u \rangle_z d}{D_{e,r}} \approx 8 - 10$$

Energy Transport. Energy transport is supplemented by radiation and conduction in the solid phase. Therefore, it is more difficult to define constant values for the heat Péclet numbers. The problem of equivalence between the heterogeneous and pseudohomogeneous models has been addressed in [51], [66].

In general the effective thermal conductivity $\lambda_{e(r,z)}$ is formed by two contributions: the quiescent bed conductivity λ_s^0 and a contribution due to the flow, i.e.,

$$\lambda_{e(r,z)} = \lambda_s^0 + C \lambda_f RePr$$

where the conductivity for the quiescent bed λ_s^0 is obtained from the correlation proposed by Zehner and Schlünder [67], while the contribution due to the flow can be found from the analysis by Vortmeyer and Berninger [66]. The constant in the above equation is chosen as $C = 0.1$ for the radial (r) direction and $C = 0.1 - 0.2$ for the axial (z) direction.

The equivalence between the heterogeneous and pseudohomogeneous models has been proved for nonreactive conditions [51]. For further information on energy transport in packed beds see [51], [52], [68–71].

Effect of Radiation. Transport by radiation is frequently ignored when estimating heat transfer coefficients. This transport mechanism depends on the temperature range for the reactor operation; for a temperature of 600 K at the reactor wall, radiation has been found to contribute up to 20 % to the overall radial heat flux [72].

The contribution of radiation to effective energy transport in packed beds has been analyzed [72], [73]. In the model presented the heat transfer is considered to be controlled by two parallel mechanisms and the overall effective thermal conductivity is assumed as

$$\lambda_{\mathrm{e},r} = \lambda^0_{\mathrm{e},r} + \lambda^r a\, d_{\mathrm{e},r}$$

where the contribution due to radiation $\lambda^{\mathrm{r}}\, ad_{\mathrm{e},\,r}$ is

$$\lambda^r a d_{\mathrm{e},r} = 4\psi\sigma\, \mathrm{d}T^3 = \left(\frac{8}{2/e - 0.264}\right)\sigma\, \mathrm{d}T^3 = C_r T^3$$

where σ is the Stefan – Boltzmann constant ($5.67 \times 10^{-8}\,\mathrm{J\,m^{-2}\,K^{-4}\,s^{-1}}$), ψ is a shape factor, and e is the particle emissivity. The treatment of this contribution is carried out by adding an additional term to the conduction term in the energy balance, i.e.,

$$\nabla \cdot \lambda_{\mathrm{e}} \cdot \nabla T = \frac{1}{r}\frac{\partial}{\partial r}\left[\left(r\,\lambda^0_{\mathrm{e},r}\frac{\partial T}{\partial r}\right) + \left(r\,C_r\,T^3\frac{\partial T}{\partial r}\right)\right] + \ldots$$
$$= \lambda_{\mathrm{e},r}\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial T}{\partial r}\right) + 3C_r\,T^2\left(\frac{\partial T}{\partial r}\right)^2 + \ldots$$

It is apparent that this contribution can become important with increasing particle emissivity and its omission would lead to conservative temperature predictions.

4.2.3. Wall Heat-Transfer Coefficient

The wall heat-transfer coefficient can be estimated from many correlations. The correlations available, however, predict heat transfer coefficients which are largely scattered. For instance, for a particle Reynolds number $Re = 100$, the heat transfer coefficient can differ by almost one order of magnitude [53]. Odendaal et al. analyzed the available correlations and compared the radial temperature profiles predicted for the solid and fluid phases. Based on the physical restriction that both profiles can never cross, most of them were discarded and only a few could be considered reliable [53].

The most often accepted correlation has been presented by Dixon et al. [74]. A thorough analysis of the estimation of this coefficient has been presented [75]. The recommended correlation has the form:

$$Nu_{\mathrm{f,\,w}} = \frac{\alpha_{\mathrm{f,\,w}}\, d}{k_{\mathrm{f}}} = \left[1 - 1.5\,(D/d)^{-1.5}\right] Pr^{1/3} Re^{0.6} \tag{4.21}$$

where $\alpha_{\mathrm{f,\,w}}$ is the fluid-to-wall heat transfer coefficient.

4.3. Further Simplifications

Despite its simplicity, the pseudohomogeneous model has proven to be a very reliable representation for transport processes in packed beds [66]. If care is taken when evaluating the transport coefficients, predictions obtained from a one-phase model will not differ significantly from those yielded by a two-phase representation. Every model has its deficiencies, thus, the heterogeneous model cannot capture the radial temperature and concentration gradients present in the pellets under reactive conditions, and the pseudohomogeneous model lacks an adequate representation of the solid phase. Windes et al. [54] have suggested an approach to achieve equivalence between the pseudohomogeneous and heterogeneous models.

The questions concerning equivalence stem from the fact that packed beds behave differently under reactive and nonreactive conditions. This was initially interpreted as a change in the heat transport coefficients under reactive conditions [76]. Wijngaarden and Westerterp [77] have addressed the subject in detail and provided a comprehensive explanation for the difference between reactive and nonreactive situations. For the mixing coefficients independence of chemical reaction was demonstrated by Gunn and Vortmeyer [78].

One-Dimensional Models versus Two-Dimensional Models Although radial temperature profiles can be minimized in the design of the reactor, it is not necessary to suppress radial dependence of temperature to obtain reliable predictions with one-dimensional models. In general, the sophistication of the model should never exceed that of the experimental data. For this reason, one-dimensional models have become increasingly useful.

BEEK and SINGER [79] addressed this point by assuming a weak parabolic radial dependence of the temperature profiles on the radial dimension. Then it can be shown that predictions from a one-dimensional model equal the average radial temperature $\langle T \rangle$ for a two-dimensional model [25]. The radial temperature distribution is then obtained as [25]:

$$T(r/R) \approx T_w + \left[\frac{1-(r/R)^2 + (2/B_\mathrm{i})}{1+(4/B_\mathrm{i})}\right] 2\left(\langle T \rangle - T_w\right)$$

The equivalence between the one-dimensional model and the radial average temperature for a two-dimensional model is obtained by a proper computation of the overall heat-transfer coefficient. For a parabolic temperature profile:

$$\frac{1}{U} = \frac{1}{h_w} + \frac{D}{8k_{\mathrm{e},r}}$$

A more refined approach was followed by CRIDER and FOSS [80], who solved the heat transfer problem analytically under nonreactive conditions. The equivalence of one/two-dimensional models was achieved by combining the radial heat-transfer parameters as follows:

$$\frac{1}{U} = \frac{1}{h_w} + \frac{D}{6.133\lambda_{\mathrm{e},r}}$$

This was later confirmed by HLAVACEK et al. [81] who solved the linearized problem and found identical results. An important theoretical conclusion can be drawn from this last observation; as long as only small radial temperature gradients exist, the chemical reaction only seems to have a significant effect on the axial temperature dependence. Under these circumstances, the radial temperature dependence can be described via a radially lumped model.

Example. The above analysis is illustrated by solving for the steady-state temperature and concentration profiles in a typical industrial reactor with the partial oxidation of *o*-xylene to phthalic anhydride as an example. This highly exothermic process is carried out in heat-exchanger-type reactors. The reactor consists of a bundle of tubes with a cooling fluid circulating around the tube arrangement. The process (of German origin, but used worldwide) employs V_2O_5 on silica gel pellets as catalyst. The geometric description and kinetic information have been taken from [82].

If the pseudohomogeneous, two-dimensional model is lumped radially, i.e., if the equations are integrated across the cross-sectional area, the following steady-state, one-dimensional model results:

$$0 = -\frac{\partial}{\partial z}(u_z C_\mathrm{X}) + D_{\mathrm{e},z}\frac{\partial^2 C_\mathrm{X}}{\partial z^2} - (1-\varepsilon)\,\varrho_\mathrm{s} R\left(C_\mathrm{X}, \langle T \rangle\right) \tag{4.22}$$

$$0 = -\frac{\partial}{\partial z}\left(\varrho_\mathrm{f} C_{p,\mathrm{f}} u_z \langle T \rangle\right) + \lambda_{\mathrm{e},z}\frac{\partial^2 \langle T \rangle}{\partial z^2} - \frac{4U}{D}\left(\langle T \rangle - T_w\right) + (-\Delta H_r)(1-\varepsilon)\,\varrho_\mathrm{s} R\left(C_\mathrm{X}, \langle T \rangle\right) \tag{4.23}$$

where $R(C_\mathrm{X}, \langle T \rangle) = k_0\, p_\mathrm{O}\, p_\mathrm{X} \exp(-E_\mathrm{a}/R_\mathrm{u} \langle T \rangle)$ represents the rate of reaction, and p_X and p_O represent the partial pressures of *o*-xylene and oxygen, respectively. The reaction is performed in excess oxygen (i.e., $p_\mathrm{O}/p_\mathrm{tot} = 0.21 \approx$ constant). Although the reaction mechanism for this process is completed by parallel and consecutive reactions, only the main reaction is addressed here.

The results obtained with the one-dimensional (Eqs. 4.22 and 4.23) and two-dimensional models are presented in Figure 17 for two different operating conditions. The one-dimensional model predicts reactor behavior satisfactorily for the conditions of Figure 17 A ($T_w = 630$ K). For the conditions of Figure 17 B ($T_\mathrm{w} = 645$ K), however, the differences between this model and the two-dimensional models are significant. This can be better understood by analyzing the results presented in Figure 18 where the radial temperature profile is shown as a function of radial position r/R at different

axial locations. The high-temperature situation (Fig. 18 B) shows the nonlinear effect of the reaction rate and the temperature profile deviates markedly from a parabolic dependence(as shown Fig. 18 A). These results show that, for mild radial dependence of the temperature distribution, one-dimensional models can be used as a reliable design tool.

Figure 17. Comparison between one- and two-dimensional models
A) $T_w = 630$ K, $x_{x,0} = 0.00924$; B) $T_w = 645$ K, $x_{x,0} = 0.00924$
a) Two-dimensional model; b) Crider and Foss model (one-dimensional; c) Beek and Singer model (one-dimensional)
Open circles in Figures 17 A and 17 B denote axial locations for curves shown in Figures 18 A and 18 B, respectively.

4.4. Parametric Sensitivity

Since the 1960s, great improvements have been made in the design and operation of catalytic reactors. In industrial conditions, however, due to the high exothermicity of the chemical reaction, the temperature rises sharply in the catalytic bed towards a maximum or hot spot (usually located near the reactor inlet). These sharp axial temperature gradients can cause poor reaction selectivity and extreme temperatures can be responsible for rapid deactivation or even deterioration of the catalyst. Therefore, the hot spot must be kept within permissible bounds. Furthermore, the attainable conversion frequently has an upper safety limit at levels where the temperature profile becomes extremely sensitive to changes in operational and/or physicochemical parameters. Bilous and Amundson [83] termed such a reactor condition as "parametric sensitivity". Many studies have been reported on the prediction of this phenomenon, which in turn can lead the reactor to runaway operation [23], [84]. The danger inherent in running such systems is widely recognized, and the final reactor design must guarantee a safe mode of operation.

Most studies on parametric sensitivity have assumed constant temperature for the cooling medium [85–91]. This is a suitable approach for perfectly mixed coolant, or reactors employing a boiling liquid or a fluid of abnormally large heat capacity as cooling medium. However, in the more common case of molten salt circulation, the thermal gradients in the shell side cannot be neglected in the reactor model. Few papers have studied the nonisothermal situation. For more information; see [92–106].

Example. Consider again, the production of phthalic anhydride via partial oxidation of *o*-xylene in a multitube heat-exchanger-type reactor. The steady-state operation will be described by the one-dimensional pseudohomogeneous model (Eqs. 4.22 and 4.23). Parametric sensitivity can be estimated as originally proposed by Bilous and Amundson [83]. It is computed as the derivative of the variable to be analyzed with respect to one of the physicochemical parameters of the process. Thus, the parametric sensitivity (S_{ij}) of the variable χ_i with respect to the parameter π_j is defined as:

$$S_{ij} = \frac{\partial \chi_i}{\partial \pi_j}$$

In what follows the effect of the reactor wall temperature on the reactor thermal condition is analyzed, i.e., $\pi = T_w$ and $\chi = \langle T \rangle$. This is a typical problem found in industrial practice where

Figure 18. Radial temperature profiles
A) $T_w = 630$ K, $x_{\mathrm{x},\,0} = 0.00924$; B) $T_{\mathrm{w}} = 645$ K, $x_{\mathrm{x},\,0} = 0.00924$

the thermal state of the reactor is monitored (i.e., the observed variable would be the readouts of the reactor thermocouples) and the operator acts on the cooling fluid (i.e., the manipulated variable would be the temperature or coolant flow rate) to keep the reactor operating near the desired state.

In order to obtain numerical values for the parametric sensitivity of the reactant concentration (S_C) and the bed temperature (S_T), the governing equations are differentiated with respect to the wall temperature, i.e.,

$$0 = -\frac{\partial}{\partial z}\left(u_z S_C\right) + D_{\mathrm{e},z}\frac{\partial^2 S_C}{\partial z^2} - (1-\varepsilon)\,\varrho_{\mathrm{s}}\frac{\partial R}{\partial T_w} \tag{4.24}$$

$$0 = -\frac{\partial}{\partial z}\left(\varrho_{\mathrm{f}} C_{p,\mathrm{f}} u_z S_T\right) + k_{\mathrm{e},z}\frac{\partial^2 S_T}{\partial z^2} - \frac{4U}{D}\left(S_T - 1\right) + \left(-\Delta H_r\right)(1-\varepsilon)\,\varrho_{\mathrm{s}}\frac{\partial R}{\partial T_{\mathrm{w}}} \tag{4.25}$$

where:

$$\frac{\partial R}{\partial T_\omega} = k_0 p_{\mathrm{O}}\left(S_C + p_{\mathrm{X}}\frac{E_{\mathrm{a}}}{R_{\mathrm{u}}\langle T\rangle^2}S_T\right)\exp\left(-E_{\mathrm{a}}/R_{\mathrm{u}}\langle T\rangle\right)$$

If Equations (4.24) and (4.25) are integrated simultaneously with the reactor model (i.e., Eqs. 4.22 and 4.23), the sensitivity of the reactant conversion and bed temperature to changes in

the coolant temperature is obtained at any point of the reactor length. Of these two sensitivity profiles, only $S_T(z)$ guarantees a safe mode of operation.

The four additional boundary conditions needed are derived from the original boundary conditions, i.e.,

Inlet, $z = 0$:

$$0 = u_z S_C - D_{e,z} \frac{\partial S_C}{\partial z} \tag{4.26}$$

$$\varrho_f C_{p,f} u_z = \varrho_f C_{p,f} u_z S_T - k_{e,z} \frac{\partial S_T}{\partial z} \tag{4.27}$$

Exit, $z = L$:

$$0 = \frac{\partial S_C}{\partial z} = \frac{\partial S_T}{\partial z} \tag{4.28}$$

Figure 19. Parametric sensitivity in packed-bed reactors for different inlet temperatures and $x_{x,0} = 0.019$
A) $T_w = 620$ K and 615 K; B) $T_w = 626$ K and 625 K

In Figure 19 the axial temperature profiles for the previous example are shown for two different inlet temperatures and the normalized temperature sensitivity associated with the lower inlet temperature. Figure 19 B illustrates the concept of parametric sensitivity; a 1 K rise in the inlet temperature is sufficient to drive the reactor away from a safe operation regime. Figure 19 A, on the other hand, only shows a small difference in the reactor thermal state after a change of 5 K in the inlet temperature. Indeed the 5 K temperature increase is transmitted almost linearly along the reactor. These two situations can be better understood by inspecting the normalized temperature sensitivity associated with the lower inlet temperature operating condition. In Figure 19 A the temperature sensitivity remains almost constant along the reactor, i.e., the temperature profile should experience an almost constant increase for a temperature rise at the inlet of the reactor. In Figure 19 B, on the other hand, the temperature is predicted to grow dramatically in the vicinity of the hot spot. Furthermore, the sensitivity crosses to negative values after the hot spot axial location; this suggests a temperature overshoot promoting a high degree of conversion and mostly cooling afterwards. Indeed, the temperature profiles corresponding to the higher inlet temperature confirm the predictions extracted from analyzing the temperature sensitivity.

4.5. Flow Field Description

Usually the flow distribution in unbounded porous media is assumed to be well represented by a linear relation between the pressure drop and the fluid velocity (Darcy's law). When using such an approximation, however, two main points are disregarded:

1) Effect of the boundaries on the flow field
2) Increasing importance of the inertial effects as the flow speed increases

If the fluid obeys the Boussinesq approximation, the flow field will be governed by [110]:

$$\varrho_f \frac{\partial \mathbf{u}}{\partial t} = -\nabla p - \frac{\mu_f}{\varkappa} \mathbf{u} - \varrho_f \left[\beta_1 (T - T_0) + \beta_2 \frac{1}{C_0} (C_0 - C) \right] \boldsymbol{g} \tag{4.29}$$

$$\nabla \cdot \mathbf{u} = 0 \tag{4.30}$$

which is known as the Darcy – Oberbeck – Boussinesq model for flow through a porous medium [111].

As the flow speed increases, the *inertial terms* become important and the results of Darcy's model are inefficient in describing the momentum transfer in packed beds. The flow through porous media is now said to be described by a "*modified*" *Darcy's law*:

$$\varrho_{\mathrm{f}}\left(\frac{\partial \mathbf{u}}{\partial t}+\frac{1}{e}\mathbf{u}\cdot\boldsymbol{\nabla}\boldsymbol{u}\right)=-\boldsymbol{\nabla}p-\frac{\mu_{\mathrm{f}}}{\varkappa}\boldsymbol{u}$$
$$-\varrho_{\mathrm{f}}\left[\beta_1\left(T-T_0\right)+\beta_2\frac{1}{C_0}\left(C_0-C\right)\right]\boldsymbol{g} \tag{4.31}$$

where the inertial forces are represented by the term $\mathbf{u}\cdot\boldsymbol{\nabla}\mathbf{u}$. Even though this term arises from a formal volume averaging in the point field equations [112], its inclusion may lead to inconsistencies between boundary conditions and governing equations [113]. FORCHHEIMER [114] first proposed addition of higher order inertial terms to the relation between pressure drop and fluid velocity and modified Darcy's equation to:

$$\frac{\mathrm{d}p}{\mathrm{d}z}+a_1u_z+a_2\left(u_z\right)^2=0$$

Later he added a third-order term to fit experimental data. FORCHHEIMER'S modification for the one-dimensional flow can be formalized for two and three dimensions as [115], [116]:

$$\boldsymbol{\nabla}p-\varrho_{\mathrm{f}}\boldsymbol{g}+\frac{\mu_{\mathrm{f}}}{\varkappa}\mathbf{u}+\frac{\varrho_{\mathrm{f}}}{\varkappa}b\mathbf{u}\,|\mathbf{u}|=0$$

where b can be considered a structure property associated with inertia effects in the porous matrix. Then the momentum equation becomes:

$$\varrho_{\mathrm{f}}\frac{\partial \mathbf{u}}{\partial t}=-\boldsymbol{\nabla}p-\frac{\mu_{\mathrm{f}}}{\varkappa}\mathbf{u}-\frac{\varrho_{\mathrm{f}}}{\varkappa}b\mathbf{u}\,|\mathbf{u}|$$
$$-\varrho_{\mathrm{f}}\left[\beta_1\left(T-T_0\right)+\beta_2\frac{1}{C_0}\left(C_0-C\right)\right]\boldsymbol{g} \tag{4.32}$$

4.5.1. Boundary Conditions

Only two boundary conditions are necessary to solve the momentum equations. The classical nonslip boundary conditions are imposed on the solid walls and a given velocity profile is imposed at the entrance and exit of the reactor, i.e.,

Reactor wall ($r=R$):

$$\mathbf{u}=[0,\,0] \tag{4.33}$$

Reactor centerline ($r=0$):

$$\mathbf{u}=[0,u_z] \tag{4.34}$$

Inlet ($z=0$):

$$\mathbf{u}=[0,u_z\,(r)] \tag{4.35}$$

Exit ($z=L$):

$$\mathbf{u}=[0,u_z\,(r)] \tag{4.36}$$

4.5.2. Permeability and Inertia Coefficient

The pressure drop in a porous medium can be approximated by the Ergun correlation, a linear combination of the Carman – Kozeny and Burke – Plummer equations [117]:

$$\frac{\Delta p}{H}=\frac{150\,(1-\varepsilon)^2}{\varepsilon^3d^2}\mu u_z+\frac{1.75\,(1-\varepsilon)}{\varepsilon^3d}\varrho u_z^2$$

However, for a certain range of fluid velocities, a linear dependence of the pressure drop on the fluid velocity (namely, the Carman – Kozeny term) provides a reliable representation description. Thus, as Darcy's law proposes a linear dependence between pressure drop and fluid velocity, the above equation can be used to estimate the packing permeability $\varkappa$ and the Forchheimer correction term b as:

$$\varkappa=\frac{d^2\varepsilon^3}{150\,(1-\varepsilon)^2}$$

$$b=\frac{1.75d}{150\,(1-\varepsilon)}$$

4.5.3. Thermal-Expansion Coefficient

The thermal-expansion coefficients are tabulated for most of the fluids of interest. When not available, a satisfactory estimation can be obtained for gaseous fluids by resorting to the ideal gas law. For instance, the expansion coefficient for temperature variations can be approximated as:

$$\varrho=\frac{pM}{RT}$$

$$\frac{\partial\varrho}{\partial T}=\frac{\varrho}{T}$$

then:

$$\beta_1\approx\frac{1}{T_0}\approx 10^{-3}$$

4.5.4. Mass-Expansion Coefficient

The expansion coefficient for concentration changes is not as readily obtained as its temperature analogue. A satisfactory estimation can still be obtained by assuming ideal gas behavior. For instance, for a binary mixture A + B where the reaction A → B takes place, the fluid density can be written as:

$$\varrho = \varrho_0 \left(\frac{1}{1 + cC_{\mathrm{A}} y} \right)$$

where c stands for a combination of the initial and final molar masses:

$$c = \frac{M_{\mathrm{i}} - M_{\mathrm{f}}}{M_{\mathrm{f}}}$$

If $c < 0$, then a lower molar mass product is formed in the chemical reaction (for instance, a decomposition reaction). In contrast $c > 0$ would indicate the formation of a product with a higher molar mass (for instance, a polymerization reaction).

If a perturbation is considered in a situation where no conversion has been achieved (i.e., $\xi \to 0$), the gas density can be represented in a linear approximation as:

$$\varrho = \varrho_0 \left(1 - \beta_2 C_{\mathrm{A}} \xi\right)$$

Taking into account that $c < 1$ and $\xi < 1$, the dependence of the density on the conversion can be written as:

$$\varrho \approx \varrho_0 \left(1 - cC_{\mathrm{A}} \xi\right)$$

then:

$$\beta_2 \approx c$$

In the case of a reaction in the liquid phase, the density must be determined from an appropriate equation of state, and the expansion coefficients should be found experimentally.

4.6. Thermomechanical Effects in the Reaction System

Several phenomena can be observed when analyzing the dynamic behavior of catalytic and noncatalytic packed-bed reactors, e.g., "parametric sensitivity", "wrong-way" behavior, travelling reaction fronts, and ignition and extinction phenomena. All these temperature excursions may disappear or be too small to drive the system out of control. However, the development of thermal stresses during these temperature excursions adds a new factor to the reactor design and operation. The mechanical behavior of the catalyst pellet can be analyzed following the basic theory of elastic behavior of solids (see [118]). For a general situation the equations can be written as:

Energy balance:

$$\varrho_{\mathrm{s}} C_{p,\mathrm{s}} \frac{\partial T}{\partial t} = k_{\mathrm{s}} \boldsymbol{\nabla}^2 T - (3\lambda + 2\mu)\, \alpha T_0 \frac{\partial}{\partial t} \left(\boldsymbol{\nabla} \cdot \mathbf{u}\right) \tag{4.37}$$

Thermomechanical equations:

$$\varrho_{\mathrm{s}} \frac{\partial^2 \delta}{\partial t^2} = \mu \boldsymbol{\nabla}^2 \delta + (\lambda + \mu)\, \boldsymbol{\nabla} \left(\boldsymbol{\nabla} \cdot \delta\right) - (3\lambda + 2\mu)\, \alpha \boldsymbol{\nabla} T \tag{4.38}$$

subject to:

$$\delta_r = 0 \quad \text{at } r = 0$$
$$\sigma_{rr} = 0 \quad \text{at } r = \mathrm{R} \tag{4.39}$$

where λ and μ are the Lamé constants, α is the coefficient of linear expansion, T_0 the temperature of stressless condition, $\boldsymbol{\delta}$ is the displacement vector, and σ_{rr} are the radial stresses.

Thus, the energy balance has been augmented from its previous form (i.e., Eq. 4.5 in Section 4.1.1), by an additional term. This term represents what is known as thermoelastic dissipation. Nevertheless, the temperature fluctuations due to deformations are usually small and, for most situations, they can be neglected. A more systematic criterion is to neglect the thermoelastic dissipation term whenever the inequality below holds:

$$\frac{(3\lambda + 2\mu)^2\, \alpha^2 T_0}{(\lambda + 2\mu)\, \varrho_{\mathrm{s}} C_{p,\mathrm{s}}} << 1$$

Another noticeable feature of the above equations is the hyperbolic nature of the thermoelastic equations. There is a close connection between the coupling discussed previously and neglection of the inertia term in the equation of motion. Indeed, the possibility of omitting the coupling terms does not depend only on satisfying the previous indicated inequality, but also on

the fact that the strain rates must be of the same order as the cooling or heating rates. This implies that the temporal behavior of the displacement vector closely follows the dynamic behavior of the temperature field. In other words, no pronounced lag or vibrations in the motion of the body must arise. Under these circumstances, the inertia term can be neglected and the equations become decoupled [119].

This model is completed by the compability and equilibrium equations (see Chap. 8 in [118]).

4.7. Numerical Simulation

(→ Mathematics in Chemical Engineering, Chap. 7.)

Due to the strongly nonlinear nature of the equations describing reactive flows, up to now analytical techniques have failed to produce solutions for the full form of the governing equations. Nevertheless, considerable progress in understanding reaction systems has been made possible through the application of analytical techniques to some limiting situations. For instance, since 1980 a wealth of information has been accumulated that shows results based on the use of large activation energy asymptotics. Although credit should be given to similar approaches for providing physical insight into many reaction problems, the models described are simplified and limitations on the techniques clearly exist. To overcome these limitations the systems of governing equations, together with the appropriate boundary conditions, must normally be solved by numerical techniques.

For the application of numerical methods, a number of grid points are distributed over the physical domain or the domain is cut up into small pieces (cells). The discretization of the governing equations yields a system of algebraic equations expressing relationships between values of the different variables at neighboring grid points.

Because of finite computer resources, it is not possible to monitor the solution at every point of the region in the space on which the problem has been defined. A finite number of grid points is therefore distributed over the field. Each of these points acts as an observer, monitoring the solution locally and relaying information about it to its neighbors. In most situations a regular, logical connectivity exists between the grid points; thus, in a two-dimensional situation each grid point is surrounded by eight neighbors. Because of this structure, a duality exists. Instead of looking at grid points, every four-point group could be seen as a quadrilateral cell. Discretization of the physical domain will thus be seen as constructing a collection of cells covering the entire domain.

However, efficiency in distributing these observers should be the guiding principle; a limited, fixed number of grid points or grid cells should be arranged in such a way that the largest possible amount of information can be extracted from their use. First, the geometry of the physical domain should be approximated in an accurate way and, second, the grid points should be able to monitor all essential features of the evolving solution without leaving gaps in any region of importance.

4.7.1. Discretization of the Physical Domain

In recent years the method of Orthogonal Collocation (OC) [120] (→ Mathematics in Chemical Engineering, Chap. 7.5., → Mathematics in Chemical Engineering, Chap. 7.6.) has been used successfully in cases of moderate values of the Damköhler number [31] even when the system is highly sensitive to changes in the operating conditions [62]. However, this approach gives inappropriate results at large values of the Péclet and/or Damköhler numbers when boundary layers associated with the flow and/or chemical reaction exist.

Certainly, in combustion-type problems most of the important physics is often restricted to small parts (or "boundary layers") inside the domain. For problems of this type Finite-Difference (FD) methods are superior to OC methods because a large number of grid points can be used and computations can still be effectively performed through tri-, penta-, and/or nano-diagonal matrix calculations.

By combining the low truncation error properties of OC methods and the ability of FD to locate grid points where needed, Carey and Finlayson [121] proposed a piecewise representation of the profiles. This method known as Orthogonal Collocation on Finite Elements

(OCFE) divides the domain into elements where the properties are expanded locally in terms of orthogonal polynomials. The OCFE method is very efficient when dealing with single boundary layers [121], [122] and one-dimensional propagation phenomena [123]. Although the OCFE methods possess several advantages, they have some undesirable features such as the drastic increase of the bandwidth with the consequence of high memory and computer time requirements for some two-dimensional problems. In particular, this method is clearly outclassed by FD methods when multiple two-dimensional boundary layers displace and deform in time. In such situations, a generalized mesh is usually the proper domain discretization. To discretize the governing equations on generalized meshes, FD schemes have proven simpler and exhibit several advantages for efficient programming.

4.7.2. Discretization of the Governing Equations

Once the physical domain has been discretized appropriately and a way has been chosen to change the grid points locations in response to the evolving solution, the governing equations can be approximated on the so constructed generalized mesh. The use of a generalized mesh makes approximation of the governing partial differential equations more complicated than it would be on an orthogonal cartesian or polar grid. Two different approaches have been followed to discretize the equations in a generalized coordinate system, each having its own merits [124].

The first approach is based on the transformation of the governing equations to the generalized curvilinear coordinates. Since the transformation involves additional terms ("cross derivatives") and variable coefficients ("metrics"), the resulting equations become more complicated. The additional terms appear because of the nonorthogonality of the curvilinear coordinates in the physical space. Depending on the rearrangement of the different terms after substitution of the transformation relations, the resulting transformed equations can be obtained in a conservative or nonconservative form. For more information, see [125].

The second approach is known as the Control Volume Formation (CVF). It takes into account the fact that the governing equations frequently represent the conservation of a transported quantity for an infinitesimally small control volume; thus, the conservation equations can easily be written for any arbitrary control volume of finite size. The approach consists of dividing the physical domain into smaller "cells" and rewritting the governing equations for these finite-size control volumes. In what follows, compressibility effects are neglected and the fluid and solid heat capacities are assumed to be constant.

The conservation law (the energy balance, for instance) applied to a control volume V is

$$\frac{\partial}{\partial t}\int_V \overline{\varrho C_p}\,T\mathrm{d}V = -\int_V \boldsymbol{\nabla}\cdot\left[\varrho_{\mathrm{f}} C_{p,\mathrm{f}}\mathbf{u}T - \boldsymbol{\lambda}_{\mathrm{e}}\cdot\boldsymbol{\nabla}T\right]\mathrm{d}V + \int_V (-\Delta H_r)\,R\,(C_1,\ldots,C_{\mathrm{i}},\ldots C_{\mathrm{s}},T)\,\mathrm{d}V \quad (4.40)$$

The convective and conductive transport terms can be rewritten by using the Gauss divergence theorem as:

$$-\int_V \boldsymbol{\nabla}\cdot\left[\varrho_{\mathrm{f}} C_p^{;\mathrm{f}}\mathbf{u}T - \lambda_{\mathrm{e}}\cdot\boldsymbol{\nabla}T\right]\mathrm{d}V = \oint_s \mathbf{n}\cdot\left[\varrho_{\mathrm{f}} C_{p,\mathrm{f}}\mathbf{u}T - \lambda_{\mathrm{e}}\cdot\boldsymbol{\nabla}T\right]\mathrm{d}S \quad (4.41)$$

where S is the surface enclosing the control volume V and $\mathbf{n}$ is the outward unit normal vector on S.

If the control volume moves and deforms in time, and a Lagrangian approach is followed, the integral of the time-dependent term becomes:

$$\frac{\partial}{\partial t}\int_V \overline{\varrho C_p}\,T\mathrm{d}V = \frac{\mathrm{d}}{\mathrm{d}t}\int_V \overline{\varrho C_p}\,T\mathrm{d}V - \oint_s \mathbf{n}\cdot\mathbf{u}_{\mathrm{s}}\left(\overline{\varrho C_p}T\right)\mathrm{d}S \quad (4.42)$$

where $\mathbf{u}_{\mathrm{s}}$ is the velocity at which the enclosing surface S moves and/or deforms.

Then, the integral form of the governing equations for the control volume V can be rewritten as:

Mass balance:

$$\varepsilon \frac{\mathrm{d}}{\mathrm{d}t} \int_V C_\mathrm{i}\,\mathrm{d}V - \varepsilon \oint_\mathrm{s} \mathbf{n}\cdot\left[(\boldsymbol{u}-\mathbf{u}_\mathrm{s})\,C_\mathrm{i}\right]\mathrm{d}S$$
$$+\varepsilon \oint_\mathrm{s} \boldsymbol{n}\cdot\mathbf{D}_\mathrm{e}\cdot\boldsymbol{\nabla}C_\mathrm{i}\,\mathrm{d}S$$
$$-\int_V R\left(C_1,\ldots,C_\mathrm{i},\ldots,C_\mathrm{S},T\right)\mathrm{d}V \qquad (4.43)$$

Energy balance:

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_V \overline{\varrho C_p}\,T\mathrm{d}V = -\oint_\mathrm{s} \mathbf{n}\cdot\left[(\mathbf{u}-\mathbf{u}_\mathrm{s})\,\varepsilon\,\varrho_\mathrm{f}C_p^{;\mathrm{f}}T\right]\mathrm{d}S$$
$$+\oint_\mathrm{s} \mathbf{n}\cdot\left[(\mathbf{u}_\mathrm{s}\,(1-\varepsilon)\,\varrho_\mathrm{s}C_{p,s}T)\,\mathrm{d}S - \oint_S \mathbf{n}\cdot\lambda_\mathrm{e}\cdot\boldsymbol{\nabla}T\mathrm{d}S\right]$$
$$+\int_V (-\Delta H_r)\,R\left(C_1,\ldots,C_\mathrm{i},\ldots,C_\mathrm{S},T\right)\mathrm{d}V \qquad (4.44)$$

The discretization of the governing equations now consists of approximating the integral form on the generalized mesh formed by quadrilateral cells. These last forms of the equations are extremely useful since continuity of fluxes through the boundaries of neighboring control volumes can be easily ensured. Conservation of the transported quantity, even for the discrete numerical approximation, will thus be maintained.

Further details of numerical approximation methods are discussed in detail in → Mathematics in Chemical Engineering, Chap. 2.

5. Optimization of Chemical Reactors

Optimization means calculation of the "best way" of operating a particular unit where a chemical reaction takes place. A number of parameters must be chosen during the design process of a chemical reactor; for instance, inlet temperature and concentration of reacting components, residence time, temperature of the cooling liquid, size of the catalyst particles, and dimension of the reactor tube. All these parameters may have a critical effect on a particular design. The optimization process usually includes economical factors in a direct or indirect way. In practical calculations there are many physical or technical constraints. For example, the composition of the inlet mixture of reacting gases must be outside of explosion limits; the maximum temperature in the reactor is given by catalyst deactivation (heterogeneous systems) or by mechanical properties of the reactor tube (homogeneous systems); maximum feed in the reactor may be limited by the capacity of downstream distillation columns, etc. The optimum design of the reactor must maximize the performance and consider the process constraints. The parameters entering into the optimization calculation can have different effects, some may have only a marginal effect while others can be critical for the optimization.

The selection of the criterion of optimality (also known as *objective function* or *performance index*) is crucial for design but somewhat arbitrary so the decision to select a certain criterion will always have a "fuzzy" character.

5.1. The Objective Function for Chemical Reactors

The objective function of a chemical reactor can have different forms. A list of functions as suggested by Edgar and Himmelblau [126] is given below:

1) Maximum conversion in a given equipment
2) Maximum production per batch
3) Minimum time of operation for a prescribed conversion
4) Maximum profit with respect to volume
5) Minimum consumption of energy
6) Minimum reactor volume with respect to certain concentrations
7) Maximum concentration by adjusting optimal temperature profile
8) Maximum selectivity for given feed
9) Minimum operating cost for a running chemical reactor

Typical independent variables are: pressure, inlet temperature and concentration, flow rate of the feed, temperature of the cooling system, and diameter of the catalyst pellets.

Frequently, the objective function has a complex character. It may be desirable, for example, to maximize profit and minimize pollution of the environment. Here two objective functions are introduced and the problem is called optimization of a vector objective function. To solve this

problem an efficient point is defined [127]. The system is said to be working at an efficient point when a particular scalar objective function cannot be optimized further without degrading the optima reached for the remaining functions.

Mathematically, the optimization problem can be formulated in the following way. A given objective function must be maximized:

$$F(x_1, x_2, \ldots, x_n) = 0$$

subject to the following relations:

$$g_i(x_1, x_2, \ldots, x_n) = 0 \quad \text{with} \quad i = 1, 2, \ldots, r < n$$

and constraints:

$$h_j(x_1, x_2, \ldots, x_n) \geq 0 \quad \text{with} \quad j = 1, 2, \ldots, m$$

Mathematically, the description of the problem is represented by algebraic equations (e.g., for the nonisothermal CSTR), ordinary differential equations of initial value type (for the nonisothermal packed-bed reactor), nonlinear differential equations of boundary value type (adiabatic packed-bed reactor with external heat exchanger), or parabolic partial differential equations (packed-bed tubular reactor). Frequently, in reaction engineering, these descriptions are highly nonlinear because of the complex kinetic expressions and exponential dependence on temperature of kinetic, adsorption, and equilibrium constants.

The mathematical techniques used to solve the optimization problems in reactor design most often reported in the literature are [128]:

1) Differential calculus
2) Nonlinear programming
3) Variational methods and maximum principle
4) Dynamic programming
5) Optimization via repeated simulations

An important aspect in optimum design of chemical reactors is the parametric sensitivity of the solution. The multiparametric problems are often so complex that direct optimization can be an unaffordable, time- consuming task. However, qualitative analysis of the problem could indicate that only few independent variables significantly affect the solution and that the optimum solution is rather insensitive towards some of the other variables. Very frequently, in the industrial environment, a quasi-optimization of the reactor problem is sought which only considers the important parameters. A quasi-optimal solution can be very close to the optimum one, and has the advantage that the operating parameters can be easily adjusted and safely controlled.

5.2. Elementary Optimization Problems

5.2.1. Optimization of a Batch System

A mass balance for the consecutive reaction:

$$\mathrm{A} \xrightarrow{k_1} \mathrm{B} \xrightarrow{k_2} \mathrm{C}$$

can be easily integrated and the solution for the concentration of B, C_B is:

$$C_\mathrm{B} = C_\mathrm{A}^0 \frac{k_1}{k_2 - k_1} \left[\mathrm{e}^{-k_1 t} - \mathrm{e}^{-k_2 t} \right] \tag{5.1}$$

where C_A^0 is the initial concentration of A. The maximum concentration of B, C_B^*, can be calculated by differentiation and solving for:

$$\frac{\partial C_\mathrm{B}}{\partial t} = C_\mathrm{A}^0 \frac{k_1}{k_2 - k_1} \left[k_2 \mathrm{e}^{-k_2 t} - k_1 \mathrm{e}^{-k_1 t} \right] = 0 \tag{5.2}$$

i.e.,

$$t^* = \frac{1}{k_2 - k_1} \ln \left(\frac{k_2}{k_1} \right) \tag{5.3}$$

where $t*$ is the time for the batch operation resulting in maximum production of B. The maximum concentration of B achievable under $t*$ conditions can be calculated by substituting Equation (5.3) into Equation (5.1), i.e.,

$$C_\mathrm{B}^* = C_\mathrm{A}^0 \left(\frac{k_2}{k_1} \right)^{k_2/(k_1 - k_2)} \tag{5.4}$$

If the activation energies of both reactions are different, the maximum selectivity is also a function of the temperature T. The maximum concentration of B can then be calculated from the condition:

$$\frac{\partial C_\mathrm{B}}{\partial t} = \frac{\partial C_\mathrm{B}}{\partial T} = 0 \tag{5.5}$$

This problem cannot be solved analytically and Equation (5.5) must be solved numerically by a suitable method (e.g., Newton – Raphson) to obtain $t*$ and $T*$ (where $T*$ is the reaction temperature which results in a maximum production

of B). The maximum concentration C_B^* can then be calculated from Equation (5.1) after inserting $t*$ and $T*$. The procedure described above can be followed for any arbitrary sequence of first-order equations that can be integrated analytically. For a complex nonlinear reaction rate scheme, a simple search approach can be followed; for a given temperature the problem is integrated numerically as an initial value problem and $t*$ is determined for $\partial C_B/\partial t = 0$. Repeating the calculation for different values of T, a one-dimensional search for the optimum condition in T will result in the values of $t*$, $T*$, and C_B^*.

5.2.2. Optimization of a Continuous System (CSTR)

If the consecutive reactions described in Section 5.2.1 are carried out in a CSTR, in a similar way it can be found that:

$$t^* = \frac{1}{\sqrt{k_1 k_2}} \tag{5.6}$$

$$C_B^* = C_A^0 \frac{1}{\left(\sqrt{k_2/k_1}+1\right)^2} \tag{5.7}$$

5.2.3. Optimization of Complex Systems: Illustrative Example

Consider the following reaction scheme:

All reactions are first order with the rate constants k_i given in the form:

$$k_i = k_{0,i} \exp\left[-\frac{E_i}{R_u}\left(\frac{1}{T} - \frac{1}{658\,\mathrm{K}}\right)\right]$$

The preexponential factors and activation energies are given in Table 6.

Table 6. Values of preexponential factors and activation energies

Kinetic values	Reaction				
	1	2	3	4	5
$k_{0,i}$, s^{-1}	1.02	0.93	0.39	3.28	0.08
E_i, kJ/mol	67.00	58.70	62.80	41.90	62.80

The optimization problem consists of finding the optimal residence time and operation temperature to maximize the production of C, C_C^*. An analytical expression for C_C can be found as:

$$C_C = \frac{k_1 k_4}{k_A - k_4} \cdot \left[\frac{1 - e^{-(k_4 - k_5)t}}{k_4 - k_5} - \frac{1 - e^{-(k_A - k_5)t}}{k_A - k_5}\right] e^{-k_5 t} \tag{5.8}$$

where $k_A = k_1 + k_2 + k_3$. The problem can be solved by a search method via, for instance, the gradient method (→ Mathematics in Chemical Engineering, Chap. 10.). The results have been summarized in Table 7.

As can be seen from Table 7, the gradient method converges slowly and the maximum is rather flat in t and T. Evidently, $t = 0.40$ s, and $T = 773$ K can be chosen as reaction conditions. In this case only 0.014 is lost in selectivity; the reaction, however, can be carried out at a temperature that is 200 K lower than the optimum temperature. This represents a major energy saving. On the other hand, the residence time is five times higher than at optimum temperature which represents higher investment cost.

5.3. Optimization of Reactors by the Search Method

The optimization of a multiparametric reaction system can be accomplished by the search method. For more information, see [126].

The simplest gradient method is sufficient to illustrate the principle of the search technique. A new approximation is always selected in the gradient direction $\nabla F(\mathbf{x})$, i.e.,

$$\mathbf{x}^{k+1} = \mathbf{x}^k + h^k \nabla F\left(\mathbf{x}^k\right) \tag{5.9}$$

where the value of h^k is selected in such a way that:

$$F\left(\mathbf{x}^{k+1}\right) < F\left(\mathbf{x}^k\right) \tag{5.10}$$

This method can be easily used for problems where the gradient of the function can be calculated analytically. Otherwise, the gradient must be calculated numerically by finite differences.

Table 7. Course of iterations using the gradient method

Iteration no.	T, K	t, s	C_C, kmol/m^3	T, K	t, s	C_C, kmol/m^3
0	1073	0.50	0.019	773	0.5	0.406
1	909	0.10	0.414	773	0.45	0.409
5	915	0.12	0.422	773	0.4	0.409
16	983	0.076	0.423	858	0.19	0.419
29	983	0.076	0.423	983	0.076	0.423
33	983	0.076	0.423	983	0.076	0.423

The rate of convergence of the gradient method is good if the initial point is far from the optimum; close to the optimum, however, the rate of convergence becomes very slow. The search by gradient method can be used easily for parameters with continuous values, complications arise for integer-value parameters (e.g., number of adiabatic reactor stages). The simplest way to overcome this problem is to perform a gradient search for a sequence of fixed integer value parameters and compare the results.

Illustrative Example [129]. Optimum operating conditions are to be found for a reactor in which nitrogen monoxide is oxidized to nitrogen dioxide. A dilute mixture of nitrogen monoxide (1.5 vol % NO) in air is fed into the reactor at a rate of 50 t NO/d. The following parameters should be optimized: catalyst type, feed composition, dew point of the inlet mixture, feed temperature, temperature control in the reactor, pressure, recirculation ratio, pressure drop, degree of conversion, mass velocity, diameter of the catalyst pellets, number of catalytic stages, and length and diameter of the catalyst bed.

A number of parameters listed here can be chosen a priori based on the information about the process.

Initial Concentration. The initial concentration is 1.5 vol % NO. This is an equilibrium concentration which results from synthesis of NO from N_2 and O_2 at ca. 2200 °C. The concentration of NO in the inlet gas can be increased by liquefaction and subsequent distillation. This modification would increase the processing costs.

Catalyst Type. Experimental results indicate that activated coke is a very good catalyst because it significantly increases the reaction rate. Silica gel is also a suitable catalyst, however, the reactor volume must then be 21 times larger. The homogeneous reactor (without catalyst) would require a volume 500 times larger. A disadvantage of activated coke is that there is the possibility of combustion in the presence of NO. This can be prevented by careful reactor temperature control, i.e., the adiabatic temperature increase in the reactor must be kept low.

Feed Temperature. The reaction rate is described by a Langmuir – Hinshelwood kinetic expression, thus the reaction rate is not very dependent on temperature. The rate of the surface reaction increases with the temperature; however, the surface concentration is then lowered because of desorption. The rate of the reverse reaction:

$$2\,NO \longrightarrow N_2 + O_2$$

can be neglected at temperatures below 200 °C. The exit temperature from the high-temperature reactor is 250 °C, the outlet gas is cooled by water to 20 – 30 °C. Cooling the inlet gas to the reactor below 20 °C would require new cooling equipment which would increase the investment costs.

Dew Point of Feed. Water is a catalyst poison for the oxidation of nitrogen monoxide both on silica gel and activated coke. For a reaction gas having a dew point 0 °C the amount of catalyst must be doubled compared with dry gas feed. For a dew point of − 30 °C the amount of catalyst required increases only by 10 %. Water can be removed from the inlet gas by drying it in an adsorption drying column packed with silica gel.

Temperature Control in the Reactor. The adiabatic temperature increase for 98 % conversion of 1.5 vol % NO in the feed is only 28 °C. Part of the reaction already occurs in the drying column (50 % conversion). The temperature increase involved (14 °C) does not promote undesirable catalyst oxidation. An adiabatic multistage reactor can thus be used for the reaction.

Recirculation. A simple calculation indicates that the reaction is completed after one pass so recirculation is not necessary.

Reactor Pressure. Doubling the pressure approximately doubles the reaction rate and halves the amount of catalyst required. However, since the mixture is strongly diluted, compression will be more expensive than the saving due to a smaller reaction volume. Therefore, the inlet pressure is chosen such that it only compensates for the pressure drop in the reactor.

Data for Calculation. The rate of oxidation of NO is described by Langmuir – Hinshelwood kinetics as:

$$R = \frac{p_{\mathrm{NO}}^2 p_{\mathrm{O_2}}}{a + b p_{\mathrm{NO}}^2 + c p_{\mathrm{NO_2}} + \omega p_{\mathrm{H_2O}}}$$

The governing equations are described by the one-phase model (see Section 4.1.3) and the pressure drop by the Ergun correlation (Section 4.5.2).

The *reactor costs* C_{R} are given by:

$$C_{\mathrm{R}} = 0.99\left[128.5 t_{\mathrm{sw}} D H_{\mathrm{t}} + 77.2 t_{\mathrm{dh}} D^2\right]^{0.648}$$

where t_{sw} is the thickness of the cylindrical side wall, D the internal diameter of the reactor, H_{t} the total length of the reactor, and t_{dh} the thickness of the dished reactor head. The reactor is designed to withstand 140 kPa overpressure.

The *ventilator costs* C_{V} are:

$$C_{\mathrm{V}} = 22\,900 \frac{\Delta P_r}{(\Delta P_r + P_{\mathrm{e}} - 0.579)^{0.915}}$$

where ΔP_r is the pressure drop across the reactor and P_{e} is the total pressure in the bulk stream at the reactor exit.

The *turbine costs* C_{T} are:

$$C_{\mathrm{T}} = 122 p_{\mathrm{H}}^{0.6}\left(\frac{\Delta P_r}{\Delta P_r + P_{\mathrm{e}} - 0.579}\right)$$

where:

$$p_{\mathrm{H}} = 22\,900\left[(\Delta P_r + P_{\mathrm{e}} + 0.421)^{0.283} - 1\right]$$

To estimate the *steam costs* (C_{S}) it is assumed that the turbine uses steam with 2.76 MPa pressure. The effectiveness of the turbine is 0.68; the turbine works 8000 h/a and steam is generated for \$ 1.10/1000 kg (1966). Then:

$$C_{\mathrm{S}} = 54 p_{\mathrm{H}}\left(\frac{\Delta P_r}{\Delta P_r + P_{\mathrm{e}} - 0.579}\right)$$

To estimate the *catalyst cost* (C_{C}), the life of the catalyst is assumed to be five years. Therefore, for \$ 0.2 per kilogram of catalyst the cost is

$$C_{\mathrm{C}} = 0.018 W$$

where W is the mass of the catalyst.

The loss C_{N} that is due to unconverted NO (\$ 2.40/100 kg NO) is

$$C_{\mathrm{N}} = 3.59 \times 10^5 (1 - \xi)$$

where ξ is the degree of NO conversion in the feed.

The *overall cost* is

$$Y = C_{\mathrm{R}} + C_{\mathrm{V}} + C_{\mathrm{T}} + C_{\mathrm{S}} + C_{\mathrm{C}} + C_{\mathrm{N}}$$

The optimization calculation performed here was based on repetitive calculations of the reactor using the Box – Wilson method [130] in which the base point of the first set of trials should be arbitrarily chosen. The range of the first set of trial points in the factorial design should be quite narrow. Preliminary calculations made by varying one factor at a time indicate certain ranges within which the optimum point probably lies. These ranges are used directly as the upper and lower levels in a two-level factorial experiment (see Table 8). The half-replicate experiments, the radial line trials, and the factor levels are given in Tables 9, 10, 11, respectively.

Table 8. Two-level factorial experimental design

Standarized variable	Natural variable	Factor level	
		− 1	+ 1
x_1	y	0.97	0.99
x_2	G [a]	200	400
x_3	D_{p} [b]	0.025	0.050
x_4	Z [c]	6	8

[a] G = mass velocity.
[b] D_{p} = diameter of catalyst particle.
[c] Z = number of catalyst layers.

The average value of trials 101 – 108 is 20 488. Since the value at the center of the response surface is much less than the average of the circumferential points, the existence of curvature in the explored region is obvious. The results of trials 109 – 112 along the radial line indicate the occurrence of a minimum in trial

110. The results of the optimum design are as follows:

Table 9. Half-replicate experiments

Trial	x_1	x_2	x_3	x_4	Y
101	−1	−1	−1	−1	20 692
102	+1	−1	−1	+1	17 081
103	−1	+1	−1	+1	21 019

Table 11. Factor levels

	−2	−1	0	+1	+2
x_1	0.98	0.9825	0.985	0.9875	0.99
x_2	200.0	225.0	250.0	275.0	300.0
x_3	0.025	0.028125	0.03125	0.034375	0.375

Catalyst	activated coke
Size of catalyst	≈ 0.01 m
Composition of gas entering bed	1.50 vol % NO
Number of layers	8
Thickness of each layer	≈ 0.80 m
Mass velocity	≈ 0.34 kg m^{-2} s^{-1}
Diameter of bed	≈ 4.0 m
Temperature of entering gas	293 K
Temperature of leaving gas	≈ 331.50 K
Pressure of entering gas	≈ 11.69 kPa
Pressure of leaving gas	≈ 11.0 kPa
Fraction conversion	0.986
Dew point, entering gas	243 K
Weight of catalyst	≈ 37 850 kg
Annual costs (1966)	
Reactor	$ 8230
Blower	$ 180
Turbine	$ 120
Steam	$ 1330
Catalyst	$ 1500
Nitrogen monoxide loss	$ 5210
Total	$ 16 570

5.4. Optimum Temperature Profile and Optimization of Multistage Reactors

For reversible exothermic catalytic reactions (e.g., water–gas shift synthesis, oxidation of SO_2 to SO_3, synthesis of methanol and ammonia), the optimum temperature profile plays an important role in optimum design.

Reaction rate isolines in the $\xi - T$ phase plane are presented in Figure 20. Three generic lines (a–c) representing three different reaction rate values (for an exothermic reversible reaction) in decreasing order are shown. The locus of optimum conditions (d) connects the points of maximum conversion for a given value of the reaction rate, the equilibrium line (e) represents the locus of reaction rate $R(C,T)=0$, and the adiabatic line (f) represents the history of the reaction rate for a reaction under adiabatic conditions.

Figure 20. Reaction rate in exothermic reversible systems a)–c) Loci of constant reaction rate; d) Optimum temperature profile; e) Equilibrium curve; f) Adiabatic line

For an equilibrium reaction:

$$\nu_1 A + \nu_2 B \rightleftharpoons \nu_3 P + \nu_4 Q$$

the reaction rate is given by:

$$R = k_1 C_A^{\nu_1} C_B^{\nu_2} - k_2 C_P^{\nu_3} C_Q^{\nu_4} \tag{5.11}$$

and for the optimum temperature where the maximum rate can be achieved, the following relation holds:

$$\frac{\partial r}{\partial T} = C_A^{\nu_1} C_B^{\nu_2} \frac{\partial k_1}{\partial T} - C_P^{\nu_3} C_Q^{\nu_4} \frac{\partial k_2}{\partial T} = 0 \tag{5.12}$$

If k_1 and k_2 show an Arrhenius dependence on temperature then:

$$\frac{C_P^{\nu_3} C_Q^{\nu_4}}{C_A^{\nu_1} C_B^{\nu_2}} = \left(\frac{k_1 E_1}{k_2 E_2}\right)_{T^*} \tag{5.13}$$

where $T*$ is the optimum reaction temperature.

For equilibrium conditions the following expression holds:

$$\frac{C_P^{\nu_3} C_Q^{\nu_4}}{C_A^{\nu_1} C_B^{\nu_2}} = \left(\frac{k_1}{k_2}\right)_{T^e} \tag{5.14}$$

where T^e is the equilibrium temperature.

Combining Equations (5.13) and (5.14), gives:

$$\frac{T^*}{T^e} = \frac{1}{1 + \frac{R_n T^e}{E_2 - E_1} \ln\left(\frac{E_2}{E_1}\right)} \tag{5.15}$$

The mass of catalyst W required for processing a given molar flow rate F of reactants in an adiabatic packed bed can be calculated from:

$$\frac{W}{F} = Z = \int_0^y \frac{\mathrm{d}y}{R} \tag{5.16}$$

For the optimum temperature profile in the reactor the integral in Equation (5.16) is minimum, i.e.,

$$\frac{\partial Z}{\partial T} = \int_0^y \left(\frac{\partial r}{\partial T}\right) \frac{\mathrm{d}y}{r^2} = 0 \tag{5.17}$$

The optimum temperature profile is presented in Figure 20 (curve d).

For adiabatic tubular reactors the optimum temperature profile cannot be easily adjusted. Figure 20 reveals that optimum reaction rate is a decreasing function in the ξ vs. T diagram while the adiabatic line is an increasing function. To reconcile the different trends of optimum temperature profile and adiabatic line, heat must be withdrawn in the axial direction. The simplest configuration is cooling between adiabatic layers. This strategy of approximation the optimum temperature profile is shown in Figure 21.

Figure 21. Approximation to the optimum temperature profile
a) Optimum profile; b) Equilibrium curve; c) Adiabatic operation; d) Intermediate cooling

5.5. Optimization of a Multibed Adiabatic Reactor with Heat Exchange Between Catalytic Stages

A schematic for optimization of a n stage adiabatic packed-bed reactor is shown in Figure 22. The mass of the catalyst W is a function of the inlet temperatures of the individual stages and the degrees of conversion obtained in the different stages:

$$W = W\left(T'_1, T'_2, \ldots, T'_n, \xi''_1, \xi''_2, \ldots, \xi''_n\right)$$

Assume that the degree of conversion in the nth stage is given. It is necessary to calculate $2n-1$ variables in such a way so that the mass of the catalyst is minimal. These parameters can be calculated by differential calculus, i.e.,

$$\left(\frac{\partial Z}{\partial T'_j}\right)_{\xi''_i, T'_i (i \neq j)} = 0 \quad \text{for} \quad i, j = 1, 2, \ldots, n \tag{5.18}$$

$$\left(\frac{\partial Z}{\partial \zeta_j}\right)_{T'_i, \xi''_i (i \neq j)} = 0 \quad \text{for} \quad i, j = 1, 2, \ldots, n \tag{5.19}$$

where ξ' and T' denote inlet conversion and temperature to a tray and ξ'' and T'' denote outlet conversion and temperature. After differentiation:

$$\frac{\partial Z}{\partial T'_j} = \int_{\zeta'_j}^{\zeta''_j} \frac{\partial}{\partial T}\left(\frac{1}{R}\right) \mathrm{d}\zeta = 0 \quad \text{for} \quad i,j = 1, 2, \ldots, n$$

$$\frac{\partial Z}{\partial \zeta'_j} = \frac{\partial}{\partial \zeta''_j} = \left[\int_{\zeta'_j}^{\zeta''_j} \frac{\mathrm{d}\zeta}{R\left(T'_j\right)} + \int_{\zeta'_{j+1}}^{\zeta''_{j+1}} \frac{\mathrm{d}\zeta}{R\left(T'_{j+1}\right)}\right] \tag{5.21}$$

$$= \frac{1}{R\left(T'_j, \zeta''_j\right)} - \frac{1}{R\left(T'_{j+1}, \zeta''_{j+1}\right)} = 0 \tag{5.22}$$

i.e.,

$$R\left(T'_j, \zeta''_j\right) = R\left(T'_{j+1}, \zeta''_{j+1}\right) \quad \text{for } i,j = 1, 2, \ldots, n \tag{5.23}$$

Figure 22. Schematic of a multibed adiabatic reactor with intermediate cooling
ξ' and T' denote inlet, ξ'' and T'' denote outlet conditions

There are $2n-1$ equations (Eqs. 5.20 and 5.23) to calculate the values of the optimum parameters. Numerically, Equation (5.20) can be solved easily by transforming it to a differential equation:

$$\frac{\partial Z}{\partial \zeta} = \frac{\partial}{\partial T}\left(\frac{1}{R}\right) = f(\zeta) \tag{5.24}$$

subject to the initial condition:

$$Z = 0 \quad \text{for} \quad \zeta = 0 \tag{5.25}$$

Equation (5.24) is integrated with Equation (5.25) until $Z = 0$. The calculated exit degree of conversion and exit temperature provide a value of reaction rate R. The inlet temperature in the second stage is calculated from Equation (5.23). The process is repeated for the remaining $n-1$ stages. In a similar way adiabatic reactors can be optimized with "cold shot", i.e., cooling between stages with fresh gas [131].

1. Tanks

1.1. Description

Most stirred tanks (stirred vessels) used as chemical reactors are cylindrical with a vertical axis, and are equipped with a centrally positioned vertical shaft upon which one or more stirrers ("impellers") are mounted. This article will concentrate on these reactors, although variants such as horizontal-axis tanks (for use with high-viscosity fluids) or off-center shafts are also encountered. The ends are normally dished (as in Fig. 1), but flat ends can be used when the reaction is performed near atmospheric pressure. These tanks must be designed according to appropriate national standards.

Figure 1. Baffled stirred tank (batch)

The volume of the tank is normally determined by the residence time required, but the aspect ratio of the tank (height/diameter, *H/D*) can be selected. Bulk mixing is favored by $H/D = 1$; however, if heat must be transferred to a jacket, the *H/D* ratio must be large to maximize the exchange surface area per unit of reacting volume, so a compromise is often necessary.

Whenever possible, *wall baffles* are installed inside the vessel (Fig. 1). These baffles prevent the gross rotation ("swirl") of the contents with the stirrer, and produce axial bulk motion of the contents to achieve top-to-bottom mixing and good particle suspension. They also produce a high relative velocity between the stirrer blades and the fluid, as required for dispersion of an immiscible phase. Wall baffles are sometimes avoided in systems that are prone to fouling (polymerizers, for example) because of the risk of an uncontrolled buildup of solid, or in processes in which gas or a floating material is to be entrained in the liquid. In this case the swirling surface vortex that develops in unbaffled stirred vessels (Fig. 2) is advantageous (although it can be unstable).

Figure 2. Unbaffled stirred tank (batch)

Jackets are often fitted around the vessel to provide heat transfer. Heat-transfer jackets are, however, insufficient for many exothermic reactions in all but the smallest vessels; in addition, a coolant flow through immersed tubes inside the tank, and even through hollow baffles, is commonly used to improve heat transfer.

Stirrers are used to enhance the contacting, mixing, mass, and heat-transfer processes relevant to the desired reactions. Especially in baffled tanks, the most appropriate type of stirrer must be selected, depending on the most important duty it has to perform; this task is not always obvious in complex multiphase reaction mixtures. The duties might be:

Bulk: Overall mixing (macromixing, i.e., "blending", "homogenization"); suspension of solid particles; distribution of bubbles or drops

Local: Heat transfer to heat-exchange surfaces; dispersion of immiscible liquid or gaseous reactants; control of size of product drops, bubbles, or particles; local mixing (micromixing) of liquid reactants

A wide variety of stirrers is available: some common examples are shown in Figures 3 and 4. Selection is based initially on the viscosity of the reaction mixture. The stirrers shown in Figure 3 are suited best to viscosities below ca. 0.5 Pa · s. Then, the type of duty and the number of phases present in the mixture are considered:

1) Propellers and their modern equivalent "hydrofoil" types (for low-viscosity liquid blending or particle suspension).
2) Intermigs and helical ribbons provide axial flow (efficient for bulk mixing and particle suspension).
3) Flat-blade turbines and disk turbines provide radial flow with high shear for dispersion of immiscible phases.
4) Pitched-blade turbines provide mixed axial and radial flow for multipurpose applications.
5) Anchors (which are used without baffles, at close clearance with the vessel wall) provide only enhancement of heat transfer between very viscous liquids and a jacket with very little mixing.

Figure 3. Agitators for low-viscosity liquids ($< 0.5\,\mathrm{Pa \cdot s}$)
A) Propeller; B) Pitched – blade turbine; C) Turbine; D) Curved – blade turbine

If the aspect ratio of the tank (*H/D*) is greater than 1.5, a second stirrer on the shaft is recommended; if the ratio is greater than 2.5, a third one; and so on. Spacing of the stirrers should approximately equal the tank diameter *D*. Closer spacing is advised for stirring non-Newtonian liquids; the Intermig is particularly suitable for these. Different types of stirrers are often combined on the shaft; for example, a disk turbine near the shaft base and downflow axial stirrers above are often used in exothermic gas – liquid processes (although the gas can produce flow instabilities on the axial stirrers). If $H/D = 2$ or 3, two or three radial-flow turbines on the shaft are also common, especially in fermentors. This arrangement can provide high power for good dispersion, but the flow pattern is compartmentalized so that overall top-to-bottom mixing is poor.

For more information on stirrer selection, including special types for high shear or for self-induction of gas (in this case the stirrer is designed to draw the gas into the liquid without a gas compressor), see → Stirring.

1.2. Operation of Stirred-Tank Reactors

Stirred-tank reactors can be operated either batchwise or continuously.

Batch Reactors. Stirred-tank batch reactors are very popular because of their flexibility and convenience. The large top surface per unit volume enables reactants to be added or samples to be removed easily by a variety of methods. The large volume available is sometimes used as a stock or buffer vessel as well as reaction space. Large tank reactors are available for reactions requiring long residence times (many hours) at commercial throughput rates. High-pressure tanks are also readily available although obtaining rotary seals for large shafts and high pressures can be a difficulty.

Figure 4. Agitators for high-viscosity liquids
A) Intermig (Ekato); B) Helical ribbon; C) Anchor

By adjustment of stirrer speed, and perhaps size and type, the mixing performance can be altered to suit a particular reaction step. These characteristics lead to the widespread use of batch stirred tanks in multiproduct plants.

Continuous Reactors. Stirred tanks are also widely used as continuous reactors. These reactors have one or more steady inflowing and outflowing streams, arranged so that vessel contents are at steady state. Ideally, the local concentrations of all components in the vessel are equal.

The flow pattern in a baffled stirred-tank approaches "ideal" back mixing, which means that

all fluid elements entering the vessel are "instantly" mixed with the vessel contents, and the concentrations of all components in the vessel are equal to those in the exit stream. Ideal back mixing in real stirred reactors is often assumed but not necessarily achieved in practice, especially on a large scale. [Misleadingly, the term continuous stirred-tank reactor (CSTR) is used in reaction engineering to mean an ideally back-mixed reactor; this can lead to confusion and unrealistic design assumptions. Ideal back-mixed reactor (IBMR) would be a better term]. By altering the rotational speed of the agitator the degree of back mixing can be adjusted within the limits of mechanical feasability.

The continuous stirred reactor has advantages in process control: its first-order time lag response is amenable to stable feedback control.

Cascade of Stirred-Tank Reactors. Other flow patterns can be achieved by linking several continuous stirred-tank reactors together. When linked in sequence (cascade), the more units in the cascade, the closer the overall residence-time distribution approaches plug flow. Stirred-tank stages can be assembled vertically, with a common shaft and interstage partition baffles, as in some contactors for immiscible liquids.

The significance of the residence-time distribution on reaction behavior is discussed further in Section 4.3.

Limitations. However, whether a stirred tank with batchwise or continuous configuration is selected, several important limitations should be borne in mind. If, after successful laboratory trials, inappropriate scale-up methods are applied, limitations may not be obvious until the production plant has been commissioned; the financial implications of the resultant disappointing yield or low capacity could then be serious. Small-scale work must be carried out under conditions that can be scaled up properly; preferably, a perceived process should be "scaled down" to operate under laboratory conditions. The temptation to run laboratory tanks at the highest agitation speeds or cooling rates should therefore be resisted unless these can be reproduced on a production scale (perhaps in some tubular reactor rather than a tank). Laboratory work should include a variation of stirrer speed to establish whether the rate-determining step is a physical one (interphase mass transfer or mixing; see Section 4.2).

Heat-Transfer Limitations. The achievable rate of heat transfer is the most common limitation. Although the heat-transfer intensity of stirred-tank reactors may be adequate for many cases, some reactions must be slowed down (to decrease the rate of heat evolution) when performed in a stirred-tank reactor. Often, the heating or cooling of a batch reactor takes as long as the reaction itself. Loop reactors should be considered in such cases (see Chap. 2).

Mixing Time Limitations. There are also limitations on mixing time (usually defined as the time required after injection of a pulse of soluble tracer liquid for its concentration to be within 1 % of the final equilibrium value at all locations in the tank contents). The mixing time is usually in the region of seconds to minutes. Thus, in the case of rapid reactions (99 % complete in ≤ 10 s with low-viscosity liquids), the concentrations, and hence reaction rates, will not be uniform throughout the tank contents. Localized overheating may result if the heat-transfer system was designed with the assumption of homogeneity. The selectivity of the reaction process may be adversely affected when competing reactions occur.

Both of the above limitations are exacerbated by higher viscosities of the reaction mixture, especially if the fluid is not fully turbulent.

Limitations of Multiphase Systems. Other limitations occur in multiphase systems. *Solid particles* generally must be kept in suspension rather than float on the surface or sit in heaps at the base if full contacting is to be ensured. Axial-flow agitators in downflow mode are usual for suspension of heavy particles. Floating solids may be drawn down into the liquid phase by a surface vortex that can be formed in vessels without baffles. The bottom bearings on the shaft should be designed to resist mechanical attack when solids are present.

Dispersion of an *immiscible liquid* in the main liquid is produced in high-shear and elongational-flow regions behind the agitator blade tips. To maximize dispersion, radial-flow agitators are used in baffled tanks. Except in those cases where the fraction of the dispersed phase is low (<10 %), it can be difficult to establish which will be the dispersed (droplet) phase. In continuous tanks the phase to be dispersed

should be fed into the stirrer blade-tip region if possible. In batch tanks, especially when starting with separated phases, the agitator is placed in the desired continuous phase so that it draws the other phase in. When fine dispersion of the dispersed phase is desired to achieve rapid mass transfer and reaction between the phases, but the phases must be separated subsequently by gravity (which requires larger droplets), a compromise in droplet size must be found.

The mechanism of *gas – liquid* dispersion in stirred tanks is similar to that described above for liquid – liquid systems. If flat-bladed turbines are used, an additional complication is that the low-pressure zone behind the blades draws gas in, forming a gas "cavity". This cavity "stream lines" the blades and partially blocks their liquid discharge path, so that local bubble breakup forces and bulk circulation are both impaired; the result can be up to 60 % reduction in power transmitted at typical gas flow rates. Agitators with curved blades (concave to the flow) alleviate this problem [1], [2].

To maximize the gas contact time, the gas is often introduced under the agitator blades, with a disk forming the center of the agitator to ensure that the gas does not bypass the dispersion zone. Alternatively, the gas can be drawn in through the top surface, either by a surface vortex (Fig. 2) or via a hollow agitator shaft with a vent hole above the liquid surface and a "self-inducing" type of agitator below.

The design of two-phase stirred tanks is described in more detail in → Stirring.

Shear Forces. The local shear forces in a stirred tank are not distributed uniformly, being an order of magnitude higher near the tips of the stirrer blade (as mentioned above) than in more remote parts of the tank. Some polymerizations and fermentations are sensitive to higher shear rates so a difficult compromise must be found between shear sensitivity and adequate mixing, phase dispersion, and heat transfer.

1.3. Examples

1.3.1. Multiproduct Batch Plant

Stirred-tank reactors are often used in multiproduct batch plants where a large number of similar processes are carried out, each at a relatively small annual production. Further complications in the manufacture of fine chemicals and specialty chemicals are the complex structures of the organic molecules undergoing reaction, the large number of possible side reactions, and the varied physical states (dry powder, wet solid, paste, liquid, emulsion, etc.) of the materials being used. Therefore, reactions must be delayed until analytical results are available; the actual concentrations of reactants in feeding vessels must be measured to adjust material charges depending on the analysis; and the reaction end points must be determined by sampling and testing.

In the example given here, several stirredtank reactors of 30- and 60-m^3 capacities are used to operate 150 separate but similar processes, with a total annual production of ca. 5000 t. The tanks are required to withstand a range of corrosive conditions and are made of rubber- or glass-lined steel. Mechanical design of the agitator baffles and cooling systems is constrained by the need to attach and maintain the rubber or glass lining. In a typical process, a wet solid reactant is charged to a concentrated acid solution to dissolve the reactant. The solution is then sampled to determine the reactant concentration. A second reactant is added, the exact quantity depending on the result of the analysis. The reaction is then performed under temperature control (in some cases by the addition of ice). The reaction product is moved to another stirredtank reactor, where it is reacted with another intermediate. This second intermediate is itself the product of one or more reaction stages. In this way, complex organic molecules (e.g., with molar masses of 500 – 1500 g/mol) are built up in multiple stages. The flexibility of the stirred-tank reactor, and the opportunity to intervene and adjust concentrations and reaction conditions, are ideally suited to this kind of manufacture.

1.3.2. Continuous-Campaign Stirred-Tank Reactor

The second example of a stirred-tank reactor is used to carry out a reaction between a gas and an organic liquid, catalyzed by a transition-metal catalyst. The reaction is mass-transfer controlled, and the reactor has baffles and an ag-

itator specially designed to promote good mass transfer between the gas, the liquid, and the solid catalyst. The reactor has a working volume of $30\,m^3$, but a significant part of this volume is left unused to allow for the occasional problem of disengaging the off-gas from the liquid, which may have a tendency to foam. The major difficulty is the removal of heat since the reaction is highly exothermic. The heat is removed partly by heat exchange in the vessel and partly by operating in an excess of product, which acts as a solvent and removes heat by boiling off and being condensed and returned to the reaction mixture.

Although this reaction might be carried out in a device where mass transfer is more intense, the advantage of the stirred tank is that production can be increased by simple modifications or enhancements, since its original installation and the use of a vaporizing and condensing solvent provide a safe, self-stabilizing system of heat removal.

1.3.3. Cascade of Continuous Stirred-Tank Reactors

The third example is a cascade of four continuous stirred-tank reactors. The reaction is the nitration of an organic compound. The heat of reaction for this is 100 J/h, and compared with the previous batch and campaign operations the reactors are relatively small, having working volumes of 3.8, 1.5, 1.5, and $1.5\,m^3$. The reaction is second order, and the system is designed to give a conversion $>99.9\,\%$.

In this example, heat is removed by cooling coils, and the heat load on the first reactor is 2.2×10^6 W. The reactor internals are therefore designed to operate as a forced-circulation heat exchanger, and the agitator is designed to give a high flow rate in a well-structured flow pattern over a tightly packed coil. The first reactor has a coil area of $90\,m^2$ in a total of $5\,m^3$ overall volume, and although theoretically a second-order reaction the overall reactor volume would be more productive if the largest reactor were the last in the cascade. The need to provide the required heat-transfer area determines the first reactor's overall size.

2. Loop Reactors (see also → Bubble Columns)

2.1. Description

A loop reactor consists of a pipe through which process fluids are recirculated. Often it also contains a heat exchanger, a tank, an injection device for reactants, and a separation device. Here, loop reactors are considered in which a pump is used for recirculation of the liquid (see Fig. 5). For loop reactors in which gas buoyancy is the driving force ("gas lifts"), see → Bubble Columns.

Figure 5. General batch loop reactor
a) Circulating pump; b) Tank; c) Heat exchanger

Loop reactors can be operated in either batch (closed-loop) or continuous configuration. A *batch loop reactor* generally contains a vessel (which may or may not be agitated) that is used to receive the initial charge of reactants and may also be employed for separation of a gaseous or solid product after the reaction. In some cases the energy of the recirculating stream can be used in the form of a jet to mix tank contents.

A *continuous loop reactor* has feedstreams (generally two) entering the loop (or tank, if present) and product streams leaving it (Fig. 6). The rate of recirculation around the loop can generally be set independently of throughput rate (an exception to this is the use of an ejector for gas addition, described below). This flexibility can be used to adapt the residence-time distribution of the overall reactor to requirements of the reaction. The higher the ratio of recirculating flow to throughflow, the nearer is the overall behavior of the loop reactor to ideal back mixing. Such adjustments are sometimes made between products in multiproduct reactors by altering pump speed or switching in more or less pipework.

Figure 6. Continuous loop reactor
a) Circulating pump; b) Tank; c) Heat exchanger

Choice of the proper recirculation rate may also be influenced by the need to disperse a second phase (a gaseous or immiscible liquid reactant) in the reacting liquid. If a suitable in-line *disperser* (e.g., a jet, orifice, or "motionless mixer" in turbulent flow) is incorporated in the loop, specific energy dissipation rates for drop or bubble dispersion can be conveniently supplied, which are 10 – 100 times higher than those available in stirred tanks. Such dispersion intensities are useful to minimize the size and cost of the reactor and to maximize yields when the key reaction rates are intrinsically rapid but controlled by interphase mass-transfer rate.

The high dispersion intensity is especially valuable in gas – liquid systems, with their typically high interfacial tensions. Care must be taken if the gas is to be separated after the reaction because higher dispersion intensities produce smaller bubbles that make any subsequent separation more difficult. The energy in the recirculating liquid stream can be used to draw in a gas reactant by means of an ejector. The *Buss reactor* is based on this principle (Fig. 7) [3] and is often used for hydrogenation. It has the advantage of rapid gas – liquid mass transfer in the initial reaction zone, combined with high heat removal capability in the tubular heat exchanger.

Figure 7. Buss loop reactor
a) Tank; b) Ejector nozzle; c) Reacting liquid; d) Pump; e) Heat exchanger

2.2. Fields of Application

2.2.1. Liquid-Phase Reactions

Loop reactors are preferred to stirred vessels when a large sensible heat-transfer area per unit volume is desired. A large heat-transfer area is particularly important for temperature control of rapid exothermic reactions. This is achieved by incorporating a tubular (often multitubular) heat exchanger in the loop and using a suitable fluid for sensible or evaporative cooling.

Coupling of Azo Dyes. A recirculating loop reactor is used for the coupling stage in the continuous manufacture of a dye. The reaction under consideration is

$$\text{Diazonium salt} + \text{Coupler} \rightarrow \text{Dye}$$

At a fixed pH the reaction rate can be represented simply by

$$\frac{\mathrm{d}}{\mathrm{d}t}\,[\text{Dye}] = K_2\,[\text{Diazonium salt}]\,[\text{Coupler}]$$

The rate constant is strongly dependent on pH and on the nature of the diazonium salt and coupler.

A competing decomposition of the diazonium salt can be represented by

$$\frac{\mathrm{d}}{\mathrm{d}t}\,[\text{Decomposition product}] = K_1\,[\text{Diazonium salt}]$$

Again K_1 is very dependent on the nature of the diazonium salt and on pH. Careful control of pH during the coupling reaction is therefore extremely important. To avoid problems caused by local rises in pH that occur when the pH control agent (e.g., sodium hydroxide) is added in a stirred vessel, a recirculating loop reactor may be used.

By recirculation of the buffer solution and addition of NaOH (Fig. 8), very tight control of pH and temperature conditions at the point of reaction can be obtained.

Figure 8. Loop reactor for azo coupling
a) Pump; b) Jet mixing section

The design of the mixer section is an important feature of the system. In some examples, a dye that precipitates may adhere to the surfaces. In recirculating loop reactors, a jet system can be used to keep the precipitate away from the tube walls until it has aged sufficiently to be nonsticky.

Production of Phenol. Another example is the cleavage of cumene hydroperoxide to produce phenol and acetone, a rapid liquid-phase reaction that is highly exothermic [4]. This reaction is autocatalytic, so back mixing is advantageous. By operating in a continuous loop reactor with a recirculation ratio of about 100, the temperature rise from inlet to outlet is maintained at only a few degrees.

Oxidation of organic compounds by nitric acid is carried out in tanks having such large recirculation streams through multitubular coolers that they could be called loop reactors. Other exothermic organic reactions (e.g., alkylation, hydration, oxidation) are also performed in loop reactors because of their high heat-transfer intensity and flexibility in residence-time distribution.

Evaporative crystallizers sometimes have an external heater and pumped circulation, which effectively makes them loop reactors. Such crystallizers have higher capacities than those using the traditional thermosiphon system.

2.2.2. Two-Phase Reactions

Immiscible Liquid Phases. A loop reactor is reportedly used in the manufacture of poly(vinyl alcohol) latex. The loop reactor is chosen for two-phase reactions to achieve tight control of the dispersion and a high degree of dispersion of the second, immiscible phase. This example is an attempt at changing a process that is traditionally performed batchwise to a continuous one. Care must always be taken in such exercises because 100 % conversion is not achievable in a continuous process.

Gas – Liquid Reactions. In the rapid gas – liquid reaction process shown in Figure 9 the gas is sparged into a tall narrow tank where it encounters the recirculating liquid stream in downflow. Downward drag from the liquid slows the rise of the gas bubbles and increases bubble contact time in the tank. Another gas – liquid reaction (alkane chlorination) in a loop reactor has been described in which the gas buoyancy is used to assist circulation of the liquid.

Figure 9. Gas – liquid loop reactor
a) Pump; b) Tank; c) Heat exchanger

If use of a pump for recirculation is undesirable and gas flow is sufficient, the buoyant energy of the gas stream can provide recirculation. This type of loop reactor, known as a gas-lift or air-lift reactor is employed for some fermentations, for more details, see → Bubble Columns.

3. Practical Limitations of Stirred-Tank and Loop Reactors

Reaction Volume.

Stirred reaction vessels for near-atmospheric pressure operation are available in very large sizes (up to ca. 5000 m^3). Drives, shafts, and seals suited for large reactor sizes are, however, very expensive. Tanks intended for operation at higher pressure are limited to smaller sizes due to limitations in maximum wall thickness, weight, and cost.

Loop reactors, which are assembled from pipe, can be virtually any size. However, volumes of more than ca. 100 m^3 in the pipe section would probably entail pumps of an impractical size especially if some energy is required to drive an intense mixer or contactor from the flow.

Heat Transfer. Consider, for example, an exothermic reaction in which temperature is controlled by heat transfer to walls only (e.g., a cooling jacket). Here, the heat removal capability is related to the wall area πHD, whereas the heat generation rate is proportional to the reaction volume $\pi HD^2/4$. The ratio of the two, $4/D$, therefore gives the maximum reaction heat removal capacity; thus, tubes are preferable to tanks because of their smaller diameter.

Mixing Time. Consider a fast reaction whose rate is determined by the speed of mixing of the miscible liquid reactants. To achieve a given degree of conversion in a continuous reactor, a given value of residence time/mixing time is required (this simple comparison ignores the effects of residence-time distribution). Typical values are given in Table 1 for systems with a low viscosity ($\approx$1 mPa · s) in various types of reactor. This table shows that a wide range of mixing times is available to suit various types of reaction and that the short residence time of in-line devices (coaxial jetmixer and static

mixer) can be matched by their rapid mixing performance.

Table 1. Comparison of mixing times ∗

Continuous reactors	Residence time, s	99 % Mixing time t_M, s
Laboratory scale		
Stirred tank (unbaffled)	1 → ∞	10 → 100
Stirred tank (baffled)	10 → ∞	1 → 10
Coaxial jet mixer	0.01 → 1	0.001 → 0.01
"Static mixer"	0.01 → 1	0.001 → 0.01
Plant scale		
Stirred tank (unbaffled)	10 → ∞	100 → 1000
Stirred tank (baffled)	100 → ∞	10 → 100
Coaxial jet mixer	0.1 → 10	0.01 → 0.1
"Static mixer"	0.1 → 10	0.01 → 0.1

∗ These very approximate values are for 'low' viscosity systems (∼1 mPa · s). Residence times do not include any loop pipework.

Two-Phase Dispersion. A similar comparison can be drawn between the capabilities of various reactors for mass transfer between a dispersed phase and a continuous phase. This is difficult to generalize for liquid – liquid systems because the phase ratio varies widely between systems. Therefore, performance is compared to the example of a typical gas – liquid system in which the reaction is so rapid that the overall rate is controlled by mass transfer.

The mass-transfer rate Φ_{MT} is usually described by

$$\Phi_{MT} = K_L a V (\Delta c)$$

where K_L is the mass-transfer coefficient, a is the interface area per unit volume, V is the corresponding volume, and Δc is the concentration gradient.

Again, if residence-time distribution differences are ignored (i.e., by assuming that Δc is the same function of inlet and outlet concentrations for all devices), a given degree of conversion (i.e., mass transferred) requires a given value of

$$K_L a V / \Phi_F = K_L a \tau_L$$

where Φ_F is the feed rate of the reactant and τ_L (= V/Φ_F) is the mean residence time of the liquid in the contact zone.

Various devices for gas – liquid mass transfer are compared in Table 2 [5]. Again the good performance of in-line devices is noteworthy. Turbulent flow conditions are assumed here. Higher viscosities of the liquid will result in longer mixing times and lower mass-transfer rates, especially if the flow is not turbulent. In the case of non-Newtonian fluids the performance is even lower.

4. Design Methods

4.1. Experiments

Where possible, reactor design is based on measurements of the rate constants and the orders of reaction of each important reaction step. If the reactions are other than first order, a proper selection of reactor type can be based on the optimum residence-time distribution (see Section 4.3) and the rate of reaction. Other considerations such as heat transfer, phase dispersion, and cost can also be introduced in the selection of reactor type. The size of the reactor can be established from the required degree of conversion and the rate equation of the slowest (rate-determining) step. The physical limitations of the design chosen are checked: if the reaction is very rapid the effective rate-determining step may be mixing or the interphase mass-transfer rate.

4.2. Scale-up

If detailed kinetic measurements are not possible, a convenient laboratory reactor (often a stirred vessel) is chosen and the overall performance of the reactor is measured under various reaction conditions. The effects of stirrer speed, pressure, and temperature are investigated to determine whether a physical rate limitation exists [5]. The conditions that enable optimum performance are then scaled up to the production design. Scale-up is reliable only if the laboratory work has been carried out carefully. With multiphase systems, scale-up is fraught with conflicts, and decisions about which design factors are most important must be made. Some examples are illustrated in [5].

Prediction of physical limitations such as reaction time and mass transfer rate is notoriously

Table 2. Comparison of different gas – liquid contacting devices (by permission of Butterworth & Co.) ∗

Device	$K_L a$, s^{-1}	V, m^3	$K_L a V$, m^3/s	a, m^{-1}	ε_L	Liquid mixing	Gas mixing	Power per unit volume, kW/m^3
Baffled agitated tank	0.02 – 0.2	0.002 – 100	10^{-4} – 20	∼ 200	0.9	back mixed	intermediate	0.5 – 10
Bubble column	0.05 – 0.01	0.002 – 300	10^{-5} – 3	∼ 20	0.95	approx. plug	plug	0.01 – 1
Packed tower	0.005 – 0.02	0.005 – 300	10^{-5} – 6	∼ 200	0.05	plug	approx. plug	0.01 – 0.2
Plate tower	0.01 – 0.05	0.005 – 300	10^{-5} – 15	∼ 150	0.15	intermediate	approx. plug	0.01 – 0.2
Static mixer (bubble flow)	0.1 – 2	up to 10	1 – 20	∼ 1000	0.5	approx. plug	plug	10 – 500

∗ These are orders of magnitude for comparison, not design figures. They are based on physical properties of air and water. Other considerations such as heat transfer, materials of construction, suspended solids, and hazardous liquids or gases (requiring low inventory) must obviously be taken into account.

unreliable and complex, and they should preferably be inferred from laboratory data and scaled up by using suitable correlations (→ Stirring, Chap. 4., → Stirring, Chap. 5.). Even the accuracy of various scale-up correlations is debatable. Figure 10 is an example of this for solid particle suspension; it compares the results of using various correlations to scale up the stirrer power per unit of liquid mass required to "just suspend" the particles [5]. If "scale factor = 1" is taken as the laboratory scale, movement to the right across the Figure represents scale-up to a plant-sized tank. The power input required (per unit mass) is obtained by following the curve for the chosen correlation and reading off the vertical scale. The disparity between the correlations is evident.

Figure 10. Conflicting scale-up relationships for particle suspension (by permission of Butterworth & Co.)

4.3. Residence-Time Distribution

4.3.1. Relevance

The ideal, "fully back-mixed" state has been defined in Section 1.1. The other extreme, for continuous reactors, is the "ideal plug-flow reactor" in which the residence time of all fluid elements is the same.

For a single reaction of order 1 or higher, the *required volume* for a given conversion will be greater for a fully back-mixed reactor than for a plug-flow or batch reactor (→ Principles of Chemical Reaction Engineering, Chap. 4.2.), for example, by a factor of 21.5 for 99 % conversion of a first-order reaction.

In more complicated reaction schemes, *selectivity* is also affected (→ Principles of Chemical Reaction Engineering, Chap. 2.3.). For example, for

$A \rightarrow B \rightarrow C$

plug flow will maximize the yield of B, whereas back mixing favors the formation of C. With parallel reactions,

$A \rightarrow B$ (order p in A)

$A \rightarrow C$ (order q in A)

if $p > q$, plug flow gives a high yield of B, whereas if $p < q$, maximum B is obtained from a back-mixed reactor.

4.3.2. Stirred Tanks

For the ideal, "fully back-mixed" state, the degree of conversion can be calculated from the following:

A mass balance over the reactor gives

$$\Phi_F c_i - \Phi_F c_o = V R_A$$

hence,

$$V/\Phi_F = \tau = (c_i - c_o)/R_A$$

where Φ_F is the feed rate, c_i the inlet concentration of reactant, c_o the outlet concentration of reactant, V the reacting volume, R_A the reaction rate, and τ the mean residence time.

For a first-order reaction

$$R_A = k c_v$$

where k is the reaction rate constant and c_v the concentration of reactant in the tank. With "full back mixing," $c_v = c_o$ hence,

$$\frac{c_o}{c_i} = \frac{1}{1+k\tau}$$

For a second-order reaction,

$$R = k c_v^2 = k c_o^2$$

$$\frac{c_o}{c_i} = \frac{(1+4k\tau c_i)^{1/2} - 1}{2k\tau c_i}$$

4.3.3. Loop Reactors

The *loop circulation* time t_L is given as

$$t_L = V/(\Phi_F + \Phi_R) = \tau/(1+R) \quad (1)$$

where Φ_R is the recirculation rate, $\tau\,(= V/\Phi_F)$ the mean residence time, and $R\,(= \Phi_R/\Phi_F)$ the recycle ratio. After mixing with the loop contents, the reactant concentration in the loop c_{iL} is

$$c_{iL} = (\Phi_F c_i + \Phi_R c_o)/(\Phi_F + \Phi_R) = (c_i + R c_o)/(1+R) \quad (2)$$

For second-order reaction

$$\frac{dc}{dt} = -k c_L^2$$

at

$$t = 0, c_L = c_{iL}$$

at

$$t = t_L, \frac{c_o}{c_{iL}} = \frac{1}{1+k c_{iL} t_L}$$

From Equations (1) and (2),

$$\frac{c_0}{c_i} = \frac{\left[\left(1+\frac{k\tau c_i}{1+R}\right)^2 + \left(\frac{4k\tau R c_i}{1+R}\right)\right]^{1/2} - \left(1+\frac{k\tau c}{1+R}\right)}{\left(\frac{2k\tau R c_i}{1+R}\right)}$$

Note that when $R \to \infty$

$$\frac{c_o}{c_i} = \frac{[1+4k\tau c_i]^{1/2} - 1}{2k\tau c_i}$$

corresponding to full back mixing, as above; when $R = 0$,

$$\frac{c_0}{c_i} = \frac{1}{1+k\tau c_i}$$

which is the equation for an ideal plug-flow reactor. More complex cases are dealt with in standard texts on reaction engineering [6], [7].

When a close approach to an ideal residence-time distribution cannot be assumed, design or scale-up requires the use of a mathematical model for the reactor that incorporates a description of the detailed flow patterns; this is dealt with in Chapter 5.

5. Reactor Modeling

5.1. Fitted Models

The earliest models for imperfectly mixed stirred vessels divided the reaction volume into *arbitrary mathematical zones of mixedness and segregation* [8], whose sizes and interlinking are described by parameters obtained by fitting to experimental data. The physical interpretation of the parameters is uncertain, so how they will change on scale-up is generally unpredictable (i.e., such methods are descriptive rather than predictive).

In the 1970s, "*semiphysical*" *models* of the reactions within the flow patterns were developed. One example is the "*zones-in-loops*" *model*, in which circulation patterns within the tank are described by loops of fully back-mixed zones in series [9]. Figure 11 shows this applied to a gas–liquid stirred reactor. The number of

zones to be used depends on the quality of mixing and can be obtained from measurements of the distribution of circulation times through the agitator. The usefulness of such models for scale-up therefore depends on the predictability of the circulation-time distribution, and data and correlations for this are limited.

Figure 11. "Zones-in-loops" model for gas – liquid stirred reactor (by permission of Butterworth & Co.)

Exchange flows between circulation "loops" can be incorporated into the model in an attempt to represent the local turbulent mixing between circulating streams. Such models, with large numbers of mixed cells, have been used extensively by MANN and coworkers [10]. These models still require parameters (velocity profiles and exchange rates) fitted from experimental data, so they are somewhat limited in scope for general use, although the parameters seem to be well established for single six-blade disk turbine agitators in baffled tanks in the turbulent regime.

All the models described thus far are basically one (or at best two) dimensional so they cannot describe the mixing processes in baffled tanks in fine detail.

5.2. Computational Fluid Dynamics (CFD)

With modern computers and algorithms the basic equations of flow (Navier–Stokes equations plus turbulence models) can be solved together with concentration and reaction equations at many (typically 50 000) points throughout the tank. The solutions can be converged to give a detailed description of the three-dimensional mixing patterns and local concentrations. Examples of results in the form of a vertical-section velocity vector field and a tracer concentration map are shown in Figures 12 A and 12 B, respectively.

The only parameters that have to be determined experimentally are now in the turbulence model (these parameters are nearly universal) and at the agitator boundaries (universal to each type of agitator, with modifications for extreme wall proximity), so CFD offers a facility for much more predictive reactor modeling. Suitable computer programs for liquid flows are available as commercial packages; suitable boundary conditions and turbulence models have to be chosen with care. The effects of changing tank shape, internals, agitator type, inlet and outlet position, etc., can be readily predicted. Programs for handling two-phase reactions, incorporating breakup, coalescence, and interphase mass transfer are being developed.

Figure 12. CFD analysis of stirred tanks

1. Introduction

Tubular reactors are in widespread industrial use for carrying out *homogeneous gas-phase reactions* requiring high temperature, plug-flow conditions, and high rate of heat transfer. Examples include (1) steam cracking of hydrocarbon feedstock to make olefins, (2) homogeneous dehydrochlorination of 1,2-dichloroethane to vinyl chloride, (3) chlorination of methane or chloromethane to higher chloromethanes, (4) pyrolysis of chlorodifluoromethane to tetrafluoroethylene, and (5) reaction of methane and ammonia to produce hydrogen cyanide.

Certain *liquid-phase reactions* requiring plug flow are also carried out in tubular reactors or, alternatively, in a cascade of continuously stirred tank reactors. The manufacture of ethylene glycol by hydrolysis of ethylene oxide is one such large-scale example.

Tubular reactors have found less application in *polymerization reactions*, where batch reactors often still predominate. The production of polyethylene is a notable exception.

This article deals mainly with the practical aspects of tubular reactors, with the intention of supplementing the more fundamental treatments given in → Principles of Chemical Reaction En-

gineering and → Model Reactors and Their Design Equations. Factors such as tube metallurgy, coking, quenching, heat recovery, and reactor control are addressed. A historical perspective of the evolution of reactors and of possible future directions for development is given. To illustrate the practical aspects in some depth, the following case studies have been selected:

Olefin production by steam cracking
Dehydrochlorination of 1,2-dichloroethane
Chloromethane manufacture

The concluding section examines the efficacy of free-radical kinetic models to predict via first principles the product distribution from a model industrial reaction – the cracking of ethane – at ultrashort residence times and temperatures considerably higher than those achievable commercially at present.

2. Olefin Production by Steam Cracking (→ Ethylene)

2.1. Background

Production of olefins by steam cracking of hydrocarbons provides an excellent example of the use of tubular reactors for an important petrochemical process. The reaction is highly endothermic, and the highest selectivity toward desired olefinic products is achieved at short residence times with temperatures up to 900 °C at the reactor exit, so the reactor must be designed for optimum heat transfer.

Steam cracking is the major source of ethylene. Depending mainly on the feedstock choice, and to a lesser extent on reactor configuration and operating conditions, the ethylene yield can range from as high as 80 wt % from ethane (when unconverted ethane is recycled) to as low as 20 wt % for gas oil as feedstock. Thus, with higher molar mass (heavier) feedstocks, large amounts of byproducts are produced that have a deleterious effect on process economics. The major byproducts are propene (propylene), 1,3-butadiene, and benzene. Extraction from cracker C_4 streams is virtually the only source of butadiene (→ Butadiene, Chap. 4.2.). Typical product yield from commonly used feedstocks are given in Table 1.

2.2. Chemistry of Olefin Production

The cracking of hydrocarbons occurs almost entirely by homogeneous gas-phase free-radical chain reactions [1]. In the simplest case, ethane pyrolysis, the steps can be set out as follows:

$$C_2H_6 \longrightarrow CH_3^\bullet + CH_3^\bullet \quad (1)$$

$$C_2H_6 + CH_3^\bullet \longrightarrow C_2H_5^\bullet + CH_4 \quad (2)$$

$$C_2H_5^\bullet \longrightarrow C_2H_4 + H^\bullet \quad (3)$$

$$C_2H_6 + H^\bullet \longrightarrow C_2H_5^\bullet + H_2 \quad (4)$$

Step (1) is the initiation reaction, and steps (2) – (4) are propagation reactions. The chain is terminated when any two radicals combine to form one of the stable species, for example

$$CH_3^\bullet + H^\bullet \longrightarrow CH_4$$

or

$$C_2H_5^\bullet + C_2H_5^\bullet \longrightarrow C_4H_{10}$$

If these were the only reactions to occur, the products from ethane pyrolysis would consist of ethylene and hydrogen in equimolar quantities, with methane and *n*-butane as byproducts. The amount of methane is determined by the length of the radical chain; at low conversion this can be very large (several hundred) and < 1 % methane is formed, but at industrially important ethane conversions (55 – 75 %), chain lengths of 5 to 10 are the norm, several percent methane is produced. At higher conversions, secondary reactions become important. Examples of these are

$$C_2H_4 + R^\bullet \longrightarrow C_2H_3^\bullet + RH$$

$$C_2H_3^\bullet \longrightarrow C_2H_2 + H^\bullet$$

$$2\,C_2H_3 \longrightarrow C_4H_6$$

Butadiene can undergo Diels – Alder reactions with itself; the reaction of butadiene with acetylene or ethylene leads to the formation of aromatics.

In the cracking of higher hydrocarbons, rapid decomposition of larger radicals – formed by hydrogen abstraction or by carbon – carbon bond

Table 1. Typical yields of major products from primary olefin plant feedstocks (in wt % on a once-through basis) *

Product	Feedstock				
	Ethane	Propane	*n*-Butane	Naphtha	Gas oil
Hydrogen	3.7	1.4	1.1	0.9	0.8
Methane	4.4	23.0	20.0	19.0	11.0
Ethylene	49.0	35.0	38.0	29.0	20.0
Ethane	35.0	3.5	4.0	4.4	3.5
Propene	1.8	14.5	16.5	14.5	13.0
Propane	0.2	10.0	0.5	0.5	0.6
Butadiene	1.5	2.6	3.5	4.0	4.5
Butenes	0.6	1.2	2.2	4.0	4.5
Butanes	0.9	0.0	5.0	0.4	0.2
Pentanes	4.0	1.7	2.3	3.0	4.5
Benzene	0.6	3.0	2.5	7.0	6.0
Other gasoline	2.0	2.0	3.0	8.0	12.0
Fuel oil	0.2	0.5	0.5	4.0	19.0

∗ All yields are approximate. With LPG (i.e., propane – butane) as feedstock yields are affected only by tube design and operating conditions. Naphthas and particularly gas oils have variable composition, which affects yield as well as coil design and operating conditions. Unconverted ethane and propane are usually separated from the products and recycled to the furnace.

scission similar to that in Equation (1) – is an important contributor to olefin yields, for example,

$$C_7H_{15}^{\bullet} \longrightarrow C_5H_{11}^{\bullet} + C_2H_4$$

$$C_5H_{11}^{\bullet} \longrightarrow C_3H_7^{\bullet} + C_2H_4$$

A chemical model that can simulate product yields from complex feed mixtures with sufficient accuracy to be commercially useful for a full-scale furnace simulation requires more than a hundred different species and perhaps more than a thousand reactions. The wide range of concentrations of components gives rise to stiff differential equations, which are not easy to integrate along a tubular reactor, especially when combined with accurate representation of heat transfer into the reacting gas stream. Such models have been written but tend to be proprietary and expensive. Several examples covering the cracking of ethane and propane at high conversions have been published [2], [3]. One that covers the formation of heavier byproducts more adequately than most includes about 47 species and more than 400 reactions [3].

Surprisingly, despite the complexity of this chemistry, simple first-order kinetics can provide a quite accurate representation of conversion as a function of residence time and temperature up to 70 % conversion.

The chemical reactions outlined above do not involve steam, despite the name steam cracking. Steam has two purposes as an essentially inert diluent: First, it *lowers the partial pressure* of hydrocarbon while absolute pressure is maintained above atmospheric. The steam can then be separated easily from the products downstream of the reactor by condensation. Low partial pressure has the beneficial effect of increasing olefin yield at the expense of the formation of paraffins and heavy products with low commercial value. The highest molar mass products tend to condense in the quench system downstream of the reactor. Condensation is minimized by low partial pressure.

Second, steam aids *heat transfer* from the walls of the reactor to the process fluid and is important in effecting the vaporization of heavier feedstocks such as full-range naphtha and gas-oil immediately upstream of the reactor.

The steam is not entirely inert; it *reacts with coke* deposited on the walls of the reactor and removes some of it as CO and CO_2, which are formed by the water – gas and shift reactions:

$$C + H_2O \longrightarrow CO + H_2$$

$$CO + H_2O \rightleftharpoons CO_2 + H_2$$

Coke formation, which has profoundly adverse effects on reactor operation, is discussed in more detail in Section 2.7. Typical concentrations of CO in the reactor effluent are a few hundred ppm; the concentration of CO_2 is about onetenth that of CO. These proportions increase rapidly with

increasing severity of cracking. Provision must be made in the separation section of the plant for removal of these gases to avoid contamination of ethylene by CO_2 and of hydrogen by CO. Steam also reacts to a small extent with hydrocarbons to give a host of minor products. These include the lower carboxylic acids, acetaldehyde, acetone, and phenols – all present at only a few parts per million in reactor effluent. However, most of them can have some deleterious effect (e.g., corrosion, contamination of products, and polymer formation in the separation section).

Since the process water formed from condensation of dilution steam is contaminated by phenols and carboxylic acids, continuous addition of alkali is required to control pH and prevent corrosion. A fraction of the water must be blown down rather than completely recycled to the dilution steam generator to avoid buildup of contaminants. This accounts for a significant part of the effluent BOD from an olefin plant.

2.3. The Reactor

The chemistry outlined in Section 2.2 leads to the conclusion that the highest yields of valuable olefins will be obtained by cracking at short residence time, high temperature, and low partial pressure. Rapid quenching of effluent from the reactor is required to "freeze" the product spectrum and stop further polymerization of the olefins and dienes produced to give undesirable secondary products of high molar mass. The low partial pressure also helps to prevent these secondary reactions, which are usually higher than first order.

Short residence time and low partial pressure are particularly important with heavier feedstocks such as naphtha and gas oil. The yields of olefins from ethane and propane are affected less by increased residence times. These low molar mass feeds require more heat input per tonne than heavier feeds and are less easily cracked, requiring a higher reactor outlet temperature or residence time than naphtha or gas oil to achieve viable conversions. Heavier feeds also start cracking at a significant rate at lower temperature than low molar mass alkanes, so the rapid heat input must begin at a lower temperature (ca. 100 K lower for gas oil than for ethane). With heavier feedstocks, lower partial pressures are also more important to avoid secondary reactions. Typical reactor inlet and outlet conditions and steam – hydrocarbon ratios are given in Table 2.

These requirements were discovered empirically before the advent of detailed kinetic models. In fact, full kinetic models indicate that a small but valuable increase in ethylene yield can be gained by delaying the quench for a few milliseconds after exit from the reaction zone to allow the reaction to continue adiabatically until the temperature has dropped 10 – 20 K [4].

2.4. Reactor Design

Since rapid heating to reaction temperature is required and the reaction is highly endothermic, it must be carried out in tubes with a high surface-to-volume ratio. Over the years, reactor design has evolved steadily to achieve higher and higher heat fluxes in combination with low pressure drops. The rate of progress has been determined largely by progress in metallurgy.

When the first full-range naphtha crackers were designed, cracking the naphtha in directly fired tubes was considered undesirable because of the risk of high coking rates induced by the high metal temperature required. Instead, the hydrocarbon feed was heated until cracking began and then mixed with a large volume of high-temperature steam, and the bulk of the reaction took place adiabatically with a residence time typically of > 1 s and a reactor exit temperature of only ca. 700°C.

Ethylene yields achieved with this type of reactor were only ca. 21 % when naphthas were used as feedstocks, which in a modern high-severity furnace could be expected to yield more than 30 % ethylene. Because of this and the poor heat integration achieved on early crackers, this type of reactor was superseded in the early 1960s by tubes suspended in a directly fired furnace similar to that used for lighter feedstocks. Although many attempts have been made to replace the tube – firebox type of reactor (see Section 2.8), none has gained commercial significance, and all current olefin plants use tubular reactors in fireboxes.

In the *earliest tubular furnaces* the internal diameters of the reactors (usually referred to as the coil) were 100 – 150 mm, the total lengths

Table 2. Typical temperatures at inlet and exit of reactor and steam – hydrocarbon ratio for major olefin plant feedstocks

	Ethane	Propane	*n*-Butane	Naphtha	Gas oil
Inlet temperature ∗, °C	650	650	600	600	550
Exit temperature ∗∗, °C	850	850	850	850	770
Steam/hydrocarbon ratio, m/m	0.3	0.4	0.4	0.5	0.7

∗ Inlet temperature is the temperature at which the rate of cracking becomes significant and the hydrocarbon must then be heated rapidly.
∗∗ Exit temperatures vary up to ± 30 K depending on furnace design and are significantly higher in the Millisecond furnace.

of the reactor varied between 70 and 90 m [5]. Residence times were on the order of 1 s, and the outlet temperature was ca. 800 – 820 °C for naphtha. This gave ethylene yields of 25 – 26 % from naphthas. The tubes were made of a ductile alloy with a high nickel content (e.g., Incoloy 800), which allowed them to be formed by extrusion. Metal temperatures were limited to slightly more than 1000 °C. The high ductility of the metal meant that the tubes could not be suspended vertically in the firebox but had to be supported horizontally at 1- to 2-m intervals. Reactor wall thicknesses were between 6 and 10 mm.

At the start of the run, when the tubes were free of coke, the temperature drop between the inside of the tube wall and the process fluid was on the order of 100 K, and the temperature gradient across the wall ca. 20 K. Thus, when the coil exit temperature was 820 °C, the start-of-run temperature of the external surface (skin temperature) was ca. 940 °C. During the run, coke is deposited, especially toward the exit of the tube, and the skin temperature required to maintain a steady process temperature approaches the metallurgical maximum. Typical run lengths before the tubes required decoking were 30 to 40 days.

Introduction of less ductile alloys (which means that reactor tubes must be made by centrifugal casting) [6] allowed higher metal temperatures (1080 – 1100 °C), and the tubes could be suspended vertically in the firebox because they did not stretch under their own weight. This allowed a better mechanical design of the furnace. The tubes were usually serpentine, with six or eight vertical legs joined by return bends, and several such coils were usually found in a single firebox (Fig. 1). The higher metallurgical temperature meant that the process temperature could be increased; the heat flux could be increased to achieve shorter residence times; or the run length could be increased by allowing greater buildup of coke. Designers usually took advantage of a combination of these possibilities.

Figure 1. Typical early cracker tube design
Uniform internal diameter 100 – 150 mm; 70 – 80 m length; vertically mounted once suitable alloys were available

Typical of this development was the *Lummus SRT-I furnace* (SRT stands for short residence time) introduced in the mid-1960s (→ Ethylene) [7]. This furnace had four cracking coils of 100-mm internal diameter, each with eight vertical passes and a total length of ca. 75 m. The coils were heated by a combination of gas-fired wall burners and floor burners (gas or oil). Each coil was capable of cracking ca. 2.5 t/h of hydrocarbon; the residence time was approximately 0.5 s. At a coil exit temperature of 840 °C, the ethylene yield was typically 2 – 3 % better than in the older type of furnace. Heat fluxes in this type of furnace are on the order of 100 kW/m^2.

Each coil had independent flow controllers for the hydrocarbon mixture and the steam. The exit temperatures for each coil were controlled independently by controlling the firing in the zone opposite that coil. Some interaction occurred between adjacent zones.

Many of these furnaces are still in service, and although selectivity has been increased by subsequent developments, the increase in selectivity for ethylene is not necessarily economically attractive because many of the coproducts are valuable.

The search for ever shorter residence times and lower pressure drops to give higher selectivities led to various diversions from the simple serpentine coil.

One development was to make the first one or two passes of each coil from a smaller-diameter tube. This gave a larger surface-to-volume ratio, allowing higher heat inputs to be achieved and full cracking temperature to be reached more rapidly. Overall pressure drop was also reduced. In a typical arrangement (Fig. 2), four parallel 50-mm tubes were followed by two 75-mm tubes and then a single 100-mm tube. Later Lummus SRT designs have this general layout [8].

Figure 2. Example of reactor geometry giving improved heat transfer and lower pressure drop
First four parallel tubes have ca. 50-mm internal diameter; next two parallel tubes, ca. 75-mm internal diameter; later tubes, ca. 10-cm internal diameter

An alternative was to use a large number of short tubes with a relatively small diameter. A good example of this is the *Stone & Webster USC furnace* [9] (→ Ethylene). This furnace typically uses tubes of 50-mm internal diameter in the form of U tubes, which are less than 30 m long. Each tube has a capacity of less than 1 t/h of naphtha, but up to 48 tubes are accommodated in a single firebox. Individual flow controllers for each coil would be uneconomical, and flow is therefore distributed between the coils by sonic flow across orifice plates or venturis. Residence time is about 0.25 s, and coil exit temperature can reach 870 °C.

The *Pullman – Kellog Millisecond furnace* has tubes of only 25-mm internal diameter (→ Ethylene) [10]. These tubes have no return bends and are only about 20 m long. Residence time is approximately 0.1 s, and coil outlet temperature ca. 900 °C. Decoking of tubes must be performed relatively often, which is acceptable in return for the higher selectivities achieved toward olefins. As another aid to heat transfer, "rifled" tubes are employed to increase the internal surface area in contact with the process stream.

Most modern furnaces have a total hydrocarbon feed rate of 15 – 25 t/h, and a typical olefin plant will have between 8 and possibly 20 furnaces. This allows furnaces to be taken off-line for decoking and maintenance, without causing undue changes in the loading on the separation section of the plant, which is usually a single-train unit. Table 2 gives typical physical parameters for a modern cracking furnace tube at inlet and outlet conditions.

Virtually all heat transfer to the outside of the tubes occurs by radiation from hot combustion gases in the firebox and from the refractory of the walls. Therefore, the arrangement of any tube in the firebox must not cause shadowing of adjacent tubes. The thermal conductivity of the high-temperature alloys used is not high; thus heat conduction around the circumference of the tube from the hottest areas with a full "view" of the hot refractory to shaded areas is not very large, compared with the heat fluxes required. The uneven circumferential temperature distribution means that the hottest sections must be unnecessarily hot for a given average heat flux. As the rate of coke formation has a high activation energy, this can lead to excessive coking in the hottest areas and shorter run lengths between decokes.

The designer is left with very little option than to have a single row of tubes suspended down the center of the firebox. The box must be quite wide to give sufficient optical path length for radiative heat transfer from the hot gases and, in the case of floor or roof firing, to avoid flame impingement.

2.5. Heat Recovery

Heat recovery from the reactor system falls into two separate sections, recovery of the heat from firebox gases and recovery of the sensible heat from process gases leaving the reactor at up to 900 °C.

The very high heat fluxes required – well in excess of 100 kW/m^2 in modern furnaces – coupled with the high skin temperatures, especially as the end of the run is approached, require that fireboxes be at > 1200 °C. This means that the efficiency of the radiant section of the furnace (where the reactor tubes are) is only ca. 50 %, the rest of the heat generated by combustion of the fuel being carried out of the firebox as sensible heat in the flue gas. In later furnace designs the radiant efficiency has been raised a few percent by heating the air required for combustion before it enters the furnace, often by integration with a gas turbine drive from one of the main compressors in the separation section of the plant, but heat recovery is still very important to operation of the reactor.

Efficient heat recovery from *flue gases* forms an integral part of reactor design. Heat from the flue gases is used to preheat the feedstock, including vaporization in the case of liquid feedstocks, and to superheat the dilution steam. Optimization of the overall heat integration of the entire plant usually dictates that the hydrocarbon feed be preheated to 100 – 150 °C via the low-grade heat recovered in the fractionation section of the plant and that the heat required to vaporize the dilution steam (equal to the latent heat of vaporization) be provided from elsewhere in the plant. Full heat recovery from the flue gas is therefore achieved by preheating high-pressure boiler feedwater and superheating the steam produced in the exchangers that cool the process gas. Modern furnaces achieve overall thermal efficiencies in the mid-90 % region.

The *process gas* typically leaves the reactor at 800 – 900 °C and is still rapidly reacting. As explained above, a few extra milliseconds of adiabatic reaction can increase the yields of valuable products, but the reactants must then be quenched rapidly. Quench system forms an integral part of the reactor because the temperatures do not permit valves, etc., between the reactor and the quench section.

For *lighter feedstocks* (LPG and naphtha), quenching is usually achieved in tubular heat exchangers with ca. 100 tubes in parallel with high-pressure steam raised on the outside. These are known as transfer line exchangers (TLXs, sometimes TLEs). For *heavier feeds*, direct quenching with heavy oil (i.e., without exchanger) was considered necessary to avoid rapid fouling of the narrow exchanger tubes by the heavy tars produced from gas oil. This meant a considerable loss of thermal efficiency. Recent designs of exchangers have enabled everything except the effluents from cracking vacuum gas oil to be quenched indirectly.

The design of the TLX requires careful optimization. Variables at the disposal of the designer are the tube diameter and length, and the pressure of the steam coolant. The objective is to minimize the pressure drop while achieving high heat-transfer area and, at the same time, to avoid cooling the process stream to a temperature at which a large amount of heavy ends would condense at the exit end of the tubes. This condensation increases roughly exponentially with decreasing temperature [11]. Most TLXs now operate with a steam side pressure of 100 bar with steam – water in a narrow annulus sur-rounding each individual process tube to increase the flow rate and hence the waterside heat-transfer coefficient. The internal diameter of the process tubes ranges from 20 to 35 mm. Start-of-run exit temperature is ca. 330 °C, and end-of-run temperature up to 450 °C.

2.6. Control of the Reactor

Once the basic design parameters of the cracking furnace have been determined, the product spectrum from a given feedstock is fixed within relatively narrow limits. The operator, however, can control several parameters that may significantly affect the yields from the furnace and hence the profitability. On individual furnaces, the operator can usually control the hydrocarbon feed rate, dilution steam rate, and coil exit temperature. For the furnaces as a whole, absolute pressure can be controlled within a limited range by adjusting the suction pressure of the compressor. The coil exit temperature has by far the greatest effect on product spectrum, and its effect on product yields is shown qualitatively in

Figure 3. Note that the ethylene yield increases rapidly and monotonically with exit temperature, whereas propene goes through a maximum. Modern furnaces usually operate to the right of this maximum, so the ratio of these two important products can be influenced over a considerable range by temperature adjustment. Increasing temperature increases the rate of coking, leading to shorter run and an increased methane-to-olefin ratio, which can result in constraints and increased energy consumption in the separation end of the plant.

Figure 3. Schematic showing qualitative effect of temperature on yields of major products
The values given are approximate, exact values depend on the coil geometry and feedstock

Olefin production is favored and coke deposition reduced by low partial pressures, which can be achieved by either increasing the dilution steam-to-hydrocarbon ratio or reducing the compressor suction pressure. Both of these increase energy consumption, so a fine balance exists between them to obtain maximum benefit.

The total amount of heat that can be put into the reaction tubes is also limited. It varies from furnace to furnace, depending on the firing and the amount of coke deposited. This leads to complex choices between hydrocarbon feed rate and temperature.

For these reasons, most operators have computer control and optimization for their furnaces. This optimization is performed with a model relating the yields of at least the major products from the furnaces to the controllable parameters; it is coupled to a model of the separation section of the plant and to an economic model representing the value of the products, the cost of fuel, etc. The optimizer may be run off-line to set conditions for a few days in advance, but it is more often run on-line, generally with feedback from on-line analysis of the furnace effluent. Optimization of olefin plants was discussed soon after introduction of the computer; the first such system was installed in the late 1960s [12], but several are now available [13]. These systems are expensive to install and maintain, but cash flows from olefin plants are so large that these systems can increase profitability by several million dollars per year compared to manual control.

2.7. Coking

Coking is an extremely complex subject whose mechanism is not well understood. The field has been reviewed [14]; a brief summary is given here.

Carbonaceous deposits can form basically in four locations in the furnace; these deposits are collectively known as coke. The first location is the point at which the last part of the liquid feed is evaporated in the convection section of the furnace. This was a problem on some early furnaces, but improvements in design have virtually eliminated it. The second location is at the other end of the system, at the exit of the quench where the heaviest components of the cracked product condense on the cool surfaces and gradually dehydrogenate. This increases pressure drop and reduces heat recovery. For many furnaces that crack heavy feedstocks, this coke lay down often limits run length, rather than coke deposition in the reaction section. The TLX design does not usually allow on-line decoking; the furnace must be taken off-line and the exchanger water-washed. Mitsubishi has designed an exchanger that allows on-line decoking [15], and several patents claim on-line decoking of conventional TLXs [16].

Neither of these two deposits can be regarded as true coke. They are really heavy hydrocarbon tar, with a hydrogen content of 3 – 4 %. The other two deposits can be regarded as true cokes, being extremely hard and having very low hydrogen content. They are deposited toward the end of the reactor tube itself and in the inlet of the TLX. Deposition in the inlet of the TLX seems to occur only when ethane and LPGs are used as cracking feeds. Inlet cone geometry of the TLX appears to have a significant, but not well-understood, effect on this.

Considerable evidence has accumulated [14] that deposition in the tube itself is metal catalyzed, with nickel identified as the major culprit. Many patents claim to reduce this catalytic action, either by coating the inner surface of the tubes [17], by using a low nickel alloy lining [18], or by adding a coking inhibitor continuously to the feed.

Sulfur occurs naturally in many hydrocarbon feedstocks, and this can markedly reduce the catalytic effect of the tube metal, at least in the early part of the run. Sulfur is usually added to feeds that do not contain it at a level of 50 – 100 ppm, often in the form of dimethyl disulfide. Apart from sulfur, which has been used too long to be patent protected, patents cover phosphorus compounds [19], boron compounds [20], and various combinations of tin, antimony, bismuth, copper, and other compounds [21]. None of these seem to provide a complete cure, especially on heavier feeds, and all have potential problems such as contamination of the products, contamination of the environment, or corrosion. Coking remains a major unsolved problem.

2.8. Alternatives to the Tubular Reactor

Many attempts have been made to improve on the tubular reactor for olefin production. Two of them have come close to commercial success. One was the Carbide Kureha process [22], in which the hydrocarbon was mixed directly with hot combustion gases in a tubular reactor with very short residence time (a few milliseconds). This process was developed to an advanced stage for cracking crude oil or fuel oil, but the continued ready availability of lighter feeds made it unattractive.

The Stone & Webster/Gulf process [23] cracks the hydrocarbon feed by rapid mixing with very hot solids, which are recycled via a generator that burns off deposited coke. A unit with a throughput equivalent to a conventional cracking furnace has been built and operated for several years.

Thus far no one has moved away from the conventional tubular reactor for a full-scale plant.

3. Gas-Phase Chlorocarbon Cracking Reactions

3.1. Reaction Description

The term chlorocarbon cracking reactions means reactions of the type

$$\mathrm{RCl} \longrightarrow \mathrm{Olefin} + \mathrm{HCl}$$

where RCl is an chlorinated aliphatic hydrocarbon.

Two such processes that have been used on an industrial scale are the cracking of 1,2-dichloroethane [*107-06-2*] to produce vinyl chloride [*75-01-4*] (→ Vinyl Chloride) and the cracking of 1,1,2,2-tetrachloroethane [*79-34-5*] to produce trichloroethylene [*79-01-6*] (→ Chlorinated Hydrocarbons):

$$\mathrm{CH_2ClCH_2Cl} \longrightarrow \mathrm{CH_2{=}CHCl} + \mathrm{HCl}$$

and

$$\mathrm{CHCl_2CHCl_2} \longrightarrow \mathrm{CHCl{=}CCl_2} + \mathrm{HCl}$$

The installed reactor capacity for 1,2-dichloroethane cracking is of the order of 20×10^6 t/a [24]; that for tetrachloroethane cracking was once several hundred thousands tonnes per year, but is now much reduced (probably of the order of 10×10^4 t/a) [25].

3.2. Reaction Thermodynamics

Heats of reaction and equilibrium constants are listed in Table 3. These reactions are significantly endothermic. The cracking reactions require temperatures of up to 700 K to go to completion (Fig. 4).

Table 3. Reaction heats and equilibrium constants for cracking reactions of 1,2-dichloroethane and 1,1,2,2-tetrachloroethane

Reaction	ΔH^0_{298},	log K_p						
	kJ/mol	300 K	400 K	500 K	600 K	700 K	800 K	900 K
$CH_2ClCH_2Cl \longrightarrow CH_2{=}CHCl + HCl$	72.4	−5.17	−2.02	−0.12	1.15	2.06	2.74	3.26
$CHCl_2CHCl_2 \longrightarrow CHCl{=}CCl_2 + HCl$	54.4	−1.72	0.67	2.11	3.07	3.76	4.26	4.65

Figure 4. Equilibrium conversions for 1,2-dichloroethane and 1,1,2,2-tetrachloroethane cracking reactions
a) 1,1,2,2-Tetrachloroethane, 1 bar; b) 1,1,2,2-Tetrachloroethane, 10 bar; c) 1,2-Dichloroethane, 1 bar; d) 1,2-Dichloroethane, 10 bar

3.3. Reaction Mechanism

The cracking reactions of 1,2-dichloroethane and 1,1,2,2-tetrachloroethane are thermally initiated free-radical processes that require temperatures of 470 – 520 °C to proceed at industrially significant rates.

The chain length in these reactions is very long (of the order of 10^6); as a consequence the reaction rate is extremely sensitive to impurities and to the reactor surface. This sensitivity is reflected in the wide range of published values [26–29] for the rate of 1,2-dichloroethane cracking (Table 4).

Table 4. Published rate data for 1,2-dichloroethane cracking

log A	E, kJ/mol	$k \times 10^4$, s^{-1} (450 °C)	Reference
7.06	115.1	524	[26]
7.52	121.8	512	[27]
10.81	196.8	3.9	[28]
13.35	222.3	21.0	[29]

Byproducts arise from reactions of the olefin produced [30]: the amounts of such byproducts are therefore tied to the reaction conversion. The higher the conversion, the greater are the quantities of byproducts formed.

3.4. Reactor Design and Operating Conditions

Reactor design and operating conditions are usually a compromise between conflicting factors. Some of the factors that influence design are as follows.

The reactor is only one unit (albeit the most important one) in a plant. The conditions under which it operates are therefore influenced by the design philosophy adopted for the entire process. In this type of process the pressure at which the reactor operates is determined by the need to distill HCl from vinyl chloride. To achieve this without excessive refrigeration, large-scale reactors operate (typically) at ca. 13 bar.

The reaction temperature is then chosen to give the required conversion in a "sensible" residence time (typically of the order of 10 s).

The most important factor determining the shape of these reactors is the need to achieve high rates of heat transfer to the reactant gas, which is essential because these reactions are highly endothermic. In practice, this means a narrow tube that allows high gas velocities with high rates of heat transfer.

The reactor cross section cannot, however, be too narrow because of soot and coke formation, which covers the walls and causes significant pressure drops over a period of time. Reactor dimensions are therefore a compromise between conflicting factors.

3.5. Reactor Modeling

The overall reaction rate depends on the inner surface of the reactor (see Section 3.3) and on the purity of the feedstock. Therefore, reaction rates cannot be predicted from published rate data. Rates must be measured for the specific construction material of the reactor and the reactor feedstock. In any reactor model, the overall reaction rate must be treated empirically. In

practice this means that an initiation rate is incorporated into the model that fits the measured rate over as wide as possible a range of reactor conditions.

However, the amounts of byproduct formed are to a first approximation independent of the overall reaction rate: they depend only on the degree of conversion. The basic chemistry of these byproduct-forming reactions is now well understood [30]. Sufficient published data on radical reaction rates are available [31–33] to allow comprehensive reactor models to be constructed.

Such models should be designed with the aim clearly in view. Thus, constructing an elaborate chemical model that incorporates detailed byproduct patterns has little point when the aim of the work is the estimation of heat fluxes and reactor wall temperatures.

Detailed and accurate byproduct patterns can be predicted for a wide range of reactor and operating conditions. This allows an economic optimization of the reactor and reactor operating conditions to be made.

As an example of the type of information that a detailed reactor model can produce, a comparison of total byproduct formation from 1,2-dichloroethane cracking and from 1,1,2,2-tetrachloroethane cracking is given in Figure 5.

Figure 5. Byproduct formation in cracking of 1,2-dichloroethane and 1,1,2,2-tetrachloroethane
a) 1,2-Dichloroethane; b) 1,1,2,2-Tetrachloroethane

A large difference exists in the predicted total amount of byproduct formation as a function of the degree of conversion. This difference is found in practice and explains the fact that reactors in which 1,2-dichloroethane is cracked operate at around 50 % conversion with 1 % byproducts, whereas similar reactors for 1,1,2,2-tetrachloroethane crackers run at 95 % conversion with the same quantity of byproducts.

3.6. Reactor Coking and Carbon Formation

A major problem in the operation of 1,2-dichloroethane cracking reactors is the laydown of carbonaceous material on the reactor wall, which gradually blocks the reactor. At a certain point a pressure drop builds up across the reactor, leading to plant shutdown and reactor decoke.

The rate at which coke is layed down is tied closely to the degree of cracking. The higher the degree of cracking, the faster is the rate of coking. In practice, with 1,2-dichloroethane reactors, plant operation is dominated by the requirement to keep the degree of cracking to approximately 50 %. Operation at higher values leads to unacceptably high rates of coking.

Reactor coking thus has a major economic impact on the process. The limitation of only 50 % conversion per pass results in large process recycles, with concomitantly high energy requirements.

Various methods of reactor decoking have been employed, including steaming out, burning, and shot-blasting with steel pellets.

4. Gas-Phase Halogenation Processes

4.1. Reaction Description

Gas-phase halogenation reactions cover a wide range of processes, many of which employ tubular reactors. Three examples of such reactions that are used on an industrial scale are

1) Substitutive chlorination
   $Cl_2 + RH \longrightarrow RCl + HCl$
   where RH is an alkane or substituted alkane, and RCl an alkyl chloride
2) Substitutive bromination
   $Br_2 + RH \longrightarrow RBr + HBr$
   where RH is an alkane or substituted alkane, and RBr an alkyl bromide
3) Perhalogenation
   $7\ Cl_2 + C_3H_6 \longrightarrow CCl_4 + C_2Cl_4 + 6\ HCl$

On the face of it, these reactions are very similar, but their different characteristics result in significant differences in reactor design and operation.

4.2. Substitutive Chlorination Reactors

The classic example of substitutive chlorination reactions is the chlorination of methane [*74-82-8*] or monochloromethane [*74-87-3*] to produce dichloromethane [*75-09-2*], trichloromethane [*67-66-3*], and tetrachloromethane [*56-23-5*] [34–36] (→ Chlorinated Hydrocarbons, Chap. 1.3.3.). This is a stepwise radical chain reaction, with the following overall steps:

$$CH_4 + Cl_2 \longrightarrow CH_3Cl + HCl$$

$$CH_3Cl + Cl_2 \longrightarrow CH_2Cl_2 + HCl$$

$$CH_2Cl_2 + Cl_2 \longrightarrow CHCl_3 + HCl$$

$$CHCl_3 + Cl_2 \longrightarrow CCl_4 + HCl$$

These reactions are very exothermic (ca. 100 kJ of heat evolved per mole of Cl_2 reacted). The overall reaction rate is sufficiently rapid that once initiated, the reaction must be treated as adiabatic. The rate of heat generation is much too fast to be controlled by heat exchangers.

A variety of different reactor designs have been proposed to meet this requirement. These include injection of liquid, using evaporative cooling to control the temperature [37], and addition of chlorine along the length of a gas-permeable tubular reactor to spread the heat load down the length of the reactor [38].

However, most commercial reactors employ one of two different approaches. In the first, chlorine is fed to a train of reactors in series, with cooling of the reacted mixture between reactors before the addition of more chlorine. In the second, a single reactor is used with recycle of unreacted feedstock or HCl to maintain the heat balance.

Within these two approaches, significant variations can also occur in the detailed design of the reactor. Two commercial designs that give different spectra of products and have different operating stabilities are shown in Figure 6.

Figure 6. Examples of reactor design used in chloromethane processes
For further explanation, see text.

The crucial difference between these reactor designs is in the gas mixing in the reaction zone. Thus the design shown in Figure 6 A has a well-mixed zone at the bottom of the reactor that effectively acts as a continuously stirred-tank reactor (CSTR); the major section of the reactor (80 % of the total volume) acts as a plug-flow region in which the reaction goes to completion.

In the other reactor design (Fig. 6 B), gas fed into the reactor reacts in the expanding jet, with a well-controlled proportion of back-mixing. As a consequence, these reactors behave more like plug-flow tubular reactors than like CSTR's. This can be seen both in the product pattern that can be achieved and in byproduct formation.

These reactors can be considered hybrids between back-mixed and tubular – plug flow. An interesting characteristic is that the product pattern is dependent on the absolute size of the reactor and on the reaction rate. In small reactors the reaction of back-mixed gases is far from complete and the reactors behave as CSTR's (Fig. 6 A). In large commercial reactors (of the type shown in Fig. 6 B) the reaction in the back-mixed gases is complete before the gas is entrained into the reacting jet; in these circumstances, the reactor behaves as expected for a plug-flow system.

4.2.1. Reactor Modeling

Substitutive chlorination reactions are gas-phase free-radical processes. Apart from the initiating reaction(s), the detailed chemical reaction

mechanism is well known [34–36], [39]. Reactor models can therefore be constructed that accurately reflect plant performance over a wide range of potential operating conditions. Such models can be used to optimize plant operation and to explore problems with reactor stability.

4.2.2. Reactor Coking and Soot Formation

Two distinct carbon-forming processes are encountered with substitutive chlorination reactors. The first is a slow laydown of very hard sheets of carbonaceous material on all internal reactor surfaces. This problem is not significant, and the carbon can be removed during routine plant shutdowns.

The second type of carbon formation can, however, be more serious. Conditions can be reached at which thermal breakdown of the chlorinated product occurs, leading to the formation of large quantities of highly mobile, fluffy soot that can be deposited in downstream equipment. This problem is more likely to occur at high reactor temperatures, at high depths of chlorination, in reactors that operate as well-stirred systems (e.g., Fig. 6 A).

4.3. Substitutive Bromination Reactors

The only known commercial examples of substitutive bromination reactors are used in the manufacture of fire-extinguishing agents; for example, the reaction

$$CF_2HCl + Br_2 \longrightarrow CF_2BrCl + HBr$$

is carried out in tubular reactors at 480 – 550 °C and up to 3 bar [40], [41].

Such reactions are close to thermoneutral ($\Delta H = -10$ to $+15$ kJ/mol). They are equilibrium limited, with maximum conversions of the order of 50 %.

The reaction occurs via a thermally initiated free-radical mechanism and is very similar to the equivalent reaction with chlorine.

4.3.1. Reactor Design

Because substitutive bromination is almost thermoneutral, reactor design is simple. A tubular reactor with sufficient volume to provide the residence time at the reaction temperature is all that is required.

4.3.2. Reactor Modeling

The chemistry of substitutive bromination reactions is very well understood [42]. Reactor models for this type of process provide an accurate and reliable guide to plant performance; they can be used confidently for reactor design and process optimization.

4.3.3. Reactor Coking and Carbon Formation

Carbon formation is not a problem with substitutive bromination. The crucial difference between this class of reaction and the corresponding chlorination processes discussed in Section 4.2 is that bromination reactions are carried out in an excess of halogen, which inhibits coking and carbon formation. Reaction conversions are limited by thermodynamic equilibria, so that even where the feedstock alkane : Br_2 ratio is > 1, free bromine is present in significant concentrations throughout the reactor.

4.4. Perhalogenation Reactors

4.4.1. Reaction Description

Perhalogenation is widely used on a large scale for the production of tetrachloromethane and tetrachloroethylene. A typical reaction is as follows (→ Chlorinated Hydrocarbons):

$$C_3H_6 + 7\,Cl_2 \longrightarrow CCl_4 + C_2Cl_4 + 6\,HCl$$

The process is operated at 560 – 620 °C and ca. 3 bar. The reaction is very exothermic (for the case quoted above, $\Delta H = -695$ kJ per mole of propene reacted).

The process is not limited to propene as feed. Reactor temperatures are such that a wide range of C_1, C_2, and C_3 feedstocks can be used. In particular, chlorinated residues from vinyl chloride manufacture and similar waste streams, are suitable. The reaction can be used to produce exclusively CCl_4 or C_2Cl_4 or any mixture of the two. This is achieved by recycle of the undesirable product.

4.4.2. Reactor Design and Operation

The most important factor determining reactor design in perhalogenation is the high heat of reaction. The conventional method of heat dissipation is to inject liquid with the reactor feed, using the latent heat of vaporization to evaporate the liquid and maintain the required reactor temperature. This is very similar to the reactors described in Section 4.2. The liquid used is commonly a $CCl_4 - C_2Cl_4$ mixture, which forms as a primary condensate in the process. The reactor is designed around the need to interconvert C_1 and C_2 species via the following equilibria:

$$C_2Cl_4 + Cl_2 \rightleftharpoons C_2Cl_6$$

$$C_2Cl_6 + Cl_2 \rightleftharpoons 2\ CCl_4$$

The required product split is achieved by recycling the unwanted product and by varying the chlorine excess and the reactor pressure.

Hoechst has developed an interesting variant of the perchlorination process that uses a tubular reactor. It operates up to 620 °C and 150 bar [43]. The reaction is carried out in an excess of chlorine. The adiabatic temperature increase is controlled by the composition of the organic feed.

Under these conditions, even intractable chlorinated residues such as hexachlorobenzene react to form tetrachloromethane. A sophisticated reactor design has been developed to meet the stringent temperature and pressure requirements [44], [45].

4.4.3. Reactor Modeling

The perhalogenation reaction is a thermally initiated radical chain process. The first stages of this reaction, namely, the conversion of feedstock to a $CCl_4 - C_2Cl_4$ mixture, is extremely fast and is complete within a small fraction of the reactor residence time. The chemistry of these reactions is complex, and published rate data under reactor conditions are sparse. Development of a reactor model for this part of the reaction would be a major undertaking.

The second stage of the reaction, the interconversion of CCl_4 and C_2Cl_4, is straightforward. A model of the second stage can be used to optimize the reactor for different feedstock and product requirements, and to minimize formation of byproducts.

4.4.4. Reactor Coking and Carbon Formation

Reactor coking is not a problem with perhalogenation. The formation of "fluffy" carbon can occur under two sets of conditions. The most common problem occurs when C_2Cl_4 is being made. For production of C_2Cl_4, a low chlorine excess is required; carbon is formed if the chlorine excess drops too far. Carbon can also be formed during both CCl_4 and C_2Cl_4 production if the feeds are not mixed effectively before injection into the reactor.

5. Fundamental Modeling Approaches – An Evaluation

Tubular homogeneous reactors are designed, optimized, and operated according to proprietary empirical models that have been developed over many years of accumulated operating data. These data provide sufficiently accurate means of interpolating between operating conditions and feedstock changes that have been previously established.

So-called *fundamental models* attempt to provide a mechanistic description of the reaction chemistry, incorporating molecular, free-radical, and surface species. Such models often encounter many hundreds of reactions with very different magnitudes of rate constants. Integration is time consuming and has required the development of special numerical techniques capable of treating a large system of stiff differential equations. The development and testing of fundamental models are daunting tasks for all but the simplest feedstocks, yet the intellectual challenges and technological prizes remain undimmed by time. In particular, the development of new types of reactor, identification of new operating regions, and use of cheaper feedstock can all benefit from a fundamental modeling approach.

5.1. Thermal Decomposition of Ethane

Fundamental kinetic data for ethane decomposition are provided by Sundaram and Froment

[2]. A subset of 22 reactions is selected that includes the major molecular species isolated at high temperature and ultrashort reaction time (< 10 ms), namely, CH_4, C_2H_2, C_2H_4, C_2H_6, C_3H_6, C_3H_8, and H_2. The reactions and their kinetic constants are given in Table 5. Some of the reverse reaction rate parameters are not tabulated by SUNDARAM and FROMENT. They are estimated in the kinetics program from forward rates and equilibrium data.

The experimental reactor consisted of an inductively heated graphite cylinder containing several fine longitudinal flow channels down which ethane was passed. The cracked gas was rapidly quenched at the reactor exit by contact with a cold N_2 stream. Uniform skin temperatures could be obtained with this heating arrangement, although the flow channels were too narrow to permit measurement of gas temperature. Pure ethane at 1 bar was used as feed. Carbon and hydrogen atom balances were brought to within 2 and 3 %, respectively.

The mathematical model assumes plug flow, isothermal reaction, and instantaneous quench; it accounts automatically for volume expansion. Since gas temperature cannot be measured, it is adjusted within the model until a match is obtained between the predicted and the observed ethane conversion. Estimated gas temperatures and residence times are shown across the top of Figure 7, which displays the predicted yields of C_2H_4, C_2H_2, CH_4, and H_2 versus ethane conversion. Also shown are the observed values.

Clearly, the predicted results are in very poor agreement with observations. The model predicts a continuously increasing yield of C_2H_4, whereas the results observed pass through a maximum. The model predicts virtually no acetylene formation, whereas more than 12 wt % is observed at the highest ethane conversions. The yield of CH_4 is also vastly underpredicted. Only the H_2 yields are in reasonable agreement.

The kinetics of vinyl radical ($C_2H_3^\bullet$) formation (Table 5, reactions 9, 11, 13, 16) and destruction (reactions 10, 12, 14, 15) in this model appear to be seriously in error; furthermore, an insufficient number of methane-forming reactions may be included in the model.

Interestingly, the model's predictions are not too bad up to an ethane conversion of 60 %, which is within the commercial range. This leaves the impression that a certain degree of tuning has been built into this so-called fundamental model to render it consistent with plant data.

5.2. Improving the Model

OLSON and coworkers studied the high-temperature thermal decomposition of ethane [46]. Their work indicates that the kinetics of vinyl radical formation and destruction are much faster than those estimated from the Sundaram and Froment model. At 1000 °C, for example, the rate of formation of $C_2H_3^\bullet$ from reaction 9 of Table 5 is a factor of 14 faster, whereas the rate of disappearance of $C_2H_3^\bullet$ by reaction 15 is enhanced by 4×10^5.

The model was rerun with the improved parameters given in Table 6. The predicted and observed yields are compared in Figure 8.

A dramatic improvement in prediction of the C_2H_2 yield is clear, and the predicted H_2 yields agree closely with observed values. The predicted C_2H_4 yield now passes through a maximum, although the peak value is 15 % overestimated and occurs at too high an ethane conversion in comparison with the observed value. Methane yields are similar to those predicted previously, as expected, and remain much lower than observed values.

The model seems to require still further improvement, particularly with regard to the key methane-forming reaction

$$CH_3^\bullet + C_2H_4 \longrightarrow CH_4 + C_2H_3^\bullet$$

The additional reaction

$$CH_3^\bullet + H_2 \longrightarrow CH_4 + H^\bullet$$

might also be included. This reaction is known to possess a highly curved Arrhenius plot [47] and to become increasingly important at higher temperature.

However, wide tuning of the parameters in the fundamental model beyond their uncertainty limits, merely to obtain agreement with practice, would be inappropriate.

This study demonstrates the need for further research on the chemistry and mechanism of cracking, even for one of the simplest hydrocarbon molecules, ethane, before truly fundamental predictions can be claimed.

Figure 7. Comparison of product yields of C_2H_4, C_2H_2, CH_4, and H_2 as a function of C_2H_6 conversion between Sundaram and Froment kinetic model and experiment

12.	$C_2H_3^\bullet + CH_4 \longrightarrow C_2H_4 + CH_3^\bullet$	calculated within program	
13.	$2\,C_2H_4 \longrightarrow C_2H_3^\bullet + C_2H_5^\bullet$	calculated within program	
14.	$C_2H_3^\bullet + C_2H_5^\bullet \longrightarrow 2\,C_2H_4$	3.16×10^9	0
15.	$C_2H_3^\bullet \longrightarrow C_2H_2 + H^\bullet$	2.0×10^9	1.318×10^8
16.	$H^\bullet + C_2H_2 \longrightarrow C_2H_3^\bullet$	3.98×10^{10}	5.443×10^6
17.	$2\,C_2H_5^\bullet \longrightarrow C_2H_6 + C_2H_4$	2.51×10^{10}	0
18.	$CH_3^\bullet + C_2H_5^\bullet \longrightarrow C_3H_8$	3.2×10^9	0
19.	$CH_3^\bullet + C_2H_4 \longrightarrow 1\text{-}C_3H_7^{\bullet\,a}$	1.0×10^9	8.374×10^6
20.	$1\text{-}C_3H_7^{\bullet\,a} \longrightarrow CH_3^\bullet + C_2H_4$	2.88×10^{14}	1.267×10^8
21.	$1\text{-}C_3H_7^{\bullet\,a} \longrightarrow C_3H_6 + H^\bullet$	6.31×10^{13}	1.591×10^8
22.	$C_3H_6 + H^\bullet \longrightarrow 1\text{-}C_3H_7^{\bullet\,a}$	3.63×10^{10}	1.0×10^7

[a] Primary propyl radical.

Table 6. Improved values for the Sundaram and Froment model according to [46]

No.	Reaction	k_∞, s^{-1} or $m^3\ kmol^{-1}\ s^{-1}$	E, J/kmol
9.	$H^\bullet + C_2H_4 \longrightarrow H_2 + C_2H_3^\bullet$	6.9×10^{11}	6.071×10^7
15.	$C_2H_3^\bullet \longrightarrow C_2H_2 + H^\bullet$	7.9×10^{14}	1.319×10^8

On a closing practical note, an increase in C_2H_4 yield from 47 % to a maximum of 55 % is observed when ethane conversion is increased from the current 60 % to 80 % by raising the gas temperature. The overall benefits of this require careful analysis and the fate of C_2H_2 would be a key component of this analysis.

6. Conclusions

In conclusion, some of the strengths and limitations of tubular reactors that have emerged in this article are listed below:

Strengths	Limitations
Plug flow	coking
High heat-transfer rates	temperature limits
Flexibility to different feedstocks	low capacity
	limited production flexibility for a given feedstock

Thus far, no one has abandoned the conventional tubular reactor in a full-scale plant. Its strengths, therefore, remain dominant. Progress in materials offers the prospect of reducing some of the more important disadvantages, such as tendency to coking and temperature limitations, which may make displacement of the tubular reactor even more difficult.

1. Introduction

Catalytic fixed-bed reactors are the most important type of reactor for the synthesis of large-scale basic chemicals and intermediates. In these reactors, the reaction takes place in the form of a heterogeneously catalyzed gas reaction on the surface of catalysts that are arranged as a so-called fixed bed in the reactor. In addition to the synthesis of valuable chemicals, fixed-bed reactors have been increasingly used to treat harmful and toxic substances. For example, the reaction chambers used to remove nitrogen oxides from power station flue gases constitute the largest type of fixed-bed reactors as regards reactor volume and throughput, while automobile exhaust purification represents by far the most widely employed application of fixed-bed reactors.

With regard to application and construction, it is convenient to differentiate between fixed-bed reactors for adiabatic operation and those for nonadiabatic operation. Since temperature control is one of the most important methods of influencing a chemical reaction, adiabatic reactors are used only where the heat of reaction is small, or where there is only one major reaction pathway; in these cases no adverse effects on selectivity or yield due to the adiabatic temperature development are expected. The characteristic feature of adiabatic reaction control is that the catalyst is present in the form of a uniform fixed bed that is surrounded by an outer insulating jacket (Fig. 1 A). Adiabatic reactor designs are discussed in Chapter 3.

Figure 1. Basic types of catalytic fixed-bed reactors
A) Adiabatic fixed-bed reactor; B) Multitubular fixed-bed reactor

Since the incoming reaction gases in most cases must be heated to the ignition temperature of the catalytic reaction, adiabatic reaction control is often coupled with heat exchange between the incoming and exiting reaction gas resulting

in so-called autothermal reaction control. This type of reaction control offers certain specific features and development perspectives, which are discussed in Chapter 5.

Reactions with a large heat of reaction as well as reactions that are extremely temperature-sensitive are carried out in reactors in which indirect heat exchange occurs via a circulating heat transfer medium integrated in the fixed bed.

Since in most cases the task of the heat-transfer cycle is to maintain the temperature in the fixed bed within a specific range, this concept is frequently described as an "isothermal fixed-bed reactor". However, isothermal reaction control does not provide optimum selectivity or yield in all cases, and for this reason the concept of heat exchangers integrated in the fixed bed is also being increasingly used to achieve nonisothermal temperature profiles.

The most common arrangement is the multitubular fixed-bed reactor, in which the catalyst is arranged in the tubes, and the heat carrier circulates externally around the tubes (Fig. 1 B). Fixed-bed reactors with an integrated heat supply or removal are discussed in Chapter 4.

Fixed-bed reactors for industrial syntheses are generally operated in a stationary mode (i.e., under constant operating conditions) over prolonged production runs, and design therefore concentrates on achieving an optimum stationary operation. However, the nonstationary dynamic operating mode is also of great importance for industrial operation control. In particular, fixed-bed reactors with a strongly exothermic reaction exhibit an, at times, surprising operational behavior which is discussed in more detail in Chapter 6.

Within a production plant the reactor may justifiably be regarded as the central item of apparatus. However, compared to the remaining parts of the plant for preparing the feed and for separating and working-up the products, often it is by no means the largest and most cost-intensive component. In many cases the achievable conversion in the reactor is limited for thermodynamic (equilibrium) and kinetic reasons (selectivity). It is then usual to separate the material discharged from the reactor into products and unreacted feed components (see Fig. 2), which are recycled to the feedstock. This recycling procedure involves costs

1) For product separation
2) For recycle compression
3) For repeated heating and cooling of the circulating material to the reaction temperature and the temperature of the separating device
4) Due to loss of product resulting from the need to remove part of the circulating material to limit the amount of inert substances or byproducts in the recycle stream (bleed stream).

To minimize these costs it is therefore necessary to maximize the conversion in the reactor and avoid as far as possible inert accompanying substances in the reaction mixture. With irreversible reactions (e.g., partial oxidations) the trend is therefore towards a highly concentrated, approximately stoichiometric feed composition, which may occasionally be in the explosive range. The resulting problems are discussed in Chapters 4 and 6.

2. Catalyst Forms for Fixed-Bed Reactors

The heart of a fixed-bed reactor and the site of the chemical reaction is the catalyst. The processes taking place on the catalyst may formally be subdivided into the following separate steps:

1) Diffusion of the reactants from the gas space through the outer gas – particle boundary layer, macropores, and micropores
2) Chemisorption on active centers
3) Surface reactions
4) Desorption of the products
5) Back-diffusion of the products into the gas space

Since most reactions take place with a considerable heat of reaction, a corresponding heat transport is superimposed on the mass transport.

The control of the microkinetics, consisting of micropore diffusion, chemisorption, surface reaction, and desorption, is the task of the catalyst developer and is not discussed further here. If the catalyst is specified together with its microkinetic properties, then reaction conditions (feedstock concentrations, pressure, temperature profile, and residence time) can be found that lead to optimum yields. The reaction engineer must determine these conditions and ensure that they are maintained in an industrial reactor.

Figure 2. Reaction cycle for synthesis reactions with incomplete conversion
a) Fixed-bed reactor; b) Feed preheater; c) Exit cooler; d) Recirculation compressor; e) Separation column

In the case of selectivity-sensitive multistep reactions, any deviation from the optimum values inevitably leads to a decrease in yield. This applies to deviations from the uniform residence time distribution due to flow dispersion and flow bypass phenomena in the fixed bed, as well as to deviations from uniform reaction conditions in the catalyst as a result of mass-transport resistance in the particles and the outer boundary layer [1].

The influence of mass-transport resistance in the particles can only be excluded if the critical reaction rate is substantially lower than the mass transport velocity. This leads on the one hand to the need for good external mass transfer (i.e. to reasonable flow conditions in the packed bed), as well as to short diffusion paths in catalyst particles and sufficiently large pores. On the other hand (in the case of exothermic reactions) the local reaction rate must be controlled and limited by the packed-bed temperature.

Temperature control thus plays a predominant role in selective reaction control in general, and in particular in the case of exothermic multistep reactions. Under nonadiabatic conditions, catalysts must therefore be assembled and arranged in the fixed bed in such a way as to ensure good heat transport to the heat-transfer medium.

A further requirement placed on the catalyst is a low flow pressure loss. This applies particularly if the reaction conversion in a single throughput is low, so that the reaction has to be carried out with a large circulating gas ratio (Fig. 2), as well as to off-gas purification, in which large off-gas streams must be handled with minimal additional cost.

Finally, the catalyst should be available in a sufficiently high concentration in order to keep the construction volume of the reactor low. The decisive parameters here are the specific external catalyst surface a_p (= square meters of catalyst surface per cubic meter reactor volume) for reactions controlled by external mass transfer, the catalyst fraction $1 - \varepsilon$, where ε = cubic meters of free gas space per cubic meter of reactor volume, describing the void fraction of the fixed bed.

The above requirements are to some extent contradictory, which has led to the proposition of a large number of different catalyst forms and arrangements. However, only a few of these have proved really effective in practical operation. Suitable catalyst forms and arrangements include random packings of spheres,

solid cylinders, and hollow cylinders, as well as uniformly structured catalyst packings in the form of monoliths with parallel channels, parallel stacked plates, and crossed, corrugated-plate packets (Fig. 3).

Figure 4. Temperature and concentration profiles for a partial oxidation reaction in a spherical catalyst pellet

2.1. Gas – Catalyst Mass and Heat Transfer

2.1.1. Random Packings

Industrial fixed-bed reactors are generally operated with a cross-sectional loading $G_z \geq 1$ kg gas per square meter of reactor cross section per second. This loading produces a sufficiently strong turbulence in random packing. As a result the external gas – catalyst mass-transfer resistance is small compared to the transport resistance in the catalyst pores.

However, generally the thermal conductivity of the catalyst matrix is larger than of the gas. This means that the external gas – catalyst heat transport resistance exceeds the thermal conduction resistance in the catalyst particles. The temperature and concentration conditions established in a spherical catalyst are illustrated for a partial oxidation reaction in Figure 4. The conditions can be calculated from the model equations given in → Model Reactors and Their Design Equations, Chap. 4.1.1. under the assumptions made there. An essential precondition is that the catalyst particle is uniformly exposed over its entire surface to a flow with uniform temperature and concentration. This is, of course, never the case in random packings. Figure 5 shows the local mass-transfer distribution, providing an insight into the overall highly inhomogeneous conditions. The visualization technique is based on the reaction of traces of ammonia in the gas stream with a catalyst surface impregnated with manganese chloride solution. The conversion to manganese dioxide is already so fast under ambient conditions that it practically depends only on the external mass-transfer resistance of the gas boundary layer. The intensity of the dark coloration is thus directly proportional to the local reaction rate of the surface reaction. At a constant ammonia concentration in the gas flow it is thus also proportional to the local mass transfer, and if the mass transfer and heat transfer are equivalent, also to the local heat transfer [2].

Figure 5 shows that the local conditions in random packings are much more complex than assumed in current conventional models. Nevertheless, the models for fixed beds containing a larger number of catalyst particles over the cross section can provide reliable information if it is

borne in mind that they only describe the mean value of a process that varies greatly as regards detail. For the same reason, it is inappropriate to compare model predictions with a few local temperature or concentration measurements. Indeed, a certain degree of averaging is also necessary in the measurement procedure (see Section 2.2).

Figure 5. Local mass-transfer distribution at the surface of individual cylindrical or ring-shaped catalyst pellets in a fixed-bed packing

The literature contains a number of correlation equations for the mean gas – catalyst mass transfer and heat transfer as a function of gas properties, catalyst geometry, and flow conditions [3], [4]. However, in practice they play only a minor role for catalyst packings since design and simulation calculations are frequently performed with a model that is quasi-homogeneous, at least with regard to temperature (→ Model Reactors and Their Design Equations, Chap. 4.). The reason for this are the above-mentioned strong local fluctuations, which make differentiation between the gas temperature and catalyst temperature difficult.

2.1.2. Monolith Structures

In contrast to random packings, the external heat transfer and mass transfer in monolith catalysts is much more uniform, but they can also become limiting factors at high reaction rates. This applies in particular to channel-type monoliths with narrow parallel channels, where the flow is generally laminar under industrial operating conditions. Examples include monolith catalysts with a square-channel cross section for automobile exhaust purification and for the removal of nitrogen oxides from flue gases.

Figure 6 shows results of the visualization of the local mass transfer by using the ammonia – manganese chloride reaction (Section 2.1.1). The marked decrease in coloration in the flow direction is mainly the result of the increasing consumption of ammonia in the wall boundary layer, so that the reactants diffusing to the wall have to travel an ever increasing distance from the flow core (build up of the laminar boundary layer). The depletion is particularly pronounced in the corners, since two reaction surfaces meet here. The more acute their enclosed angle, the greater is the depletion in the corner region and the smaller is the contribution of the wall surface to further heat transfer and mass transfer. The efficiency of channel monoliths of equal cross-sectional area but different shape therefore decreases in the sequence: circle, hexagon, rectangle, triangle. This is illustrated in Table 1, which gives the asymptotic dimensionless mass-transfer and heat-transfer coefficients for tubes of the above cross sections. As Figure 7 shows, the asymptotic limiting value is established after a flow length roughly corresponding to 10 times the hydraulic channel diameter. The asymptotic limiting value from Table 1 can therefore be used to perform estimation calculations in conventional industrial monolith catalysts with a large length-to-diameter ratio. For more accurate calculations the radially and axially variable velocity, concentration, and temperature profiles must also be taken into account [7].

Table 1. Asymptotic dimensionless laminar flow heat or mass-transfer coefficients $Nu = \alpha_w \cdot d_h/\lambda_G$ (constant wall conditions) and fanning friction factor f for pressure drop $\Delta p = 2f(\eta Z_L/d_h^2) \cdot v_G$ for ducts of different cross section [6]

Geometry	*Nu*	*f*	d_h
	2.47	13.33	$2a/\sqrt{3}$
	2.98	14.23	a
	3.34	15.05	$2\sqrt{3}a$
	3.66	16.00	a
	7.54	24.00	$2a$

Figure 6. Visualization of mass transfer in monolith structures (flow from left to right)
A) Square duct; B) Corrugated monolith [5]

In contrast to the monolith types discussed so far, the flow conditions in corrugated-plate monoliths (Fig. 3 C) are turbulent under normal industrial velocities. The uniformity of the mass-transfer distribution [8] depends on geometrical parameters (wave form, amplitude, wavelength, angle of incidence). The transfer coefficients are considerably higher than those of laminarly traversed channel monoliths (Fig. 6 B), but the pressure loss is also high. These structures offer considerable advantages for convective heat transport transverse to the flow direction and for transverse mixing, which are discussed in more detail in the following sections.

2.2. Flow and Pressure Loss in Fixed Beds

Conventional industrial catalyst forms differ considerably as regards pressure loss. For example, for equal mean dimensions and the same proportion of empty space, random packings generally have a considerably higher pressure loss than monolith structures, and among these, corrugated structures have a higher pressure loss than monoliths with straight parallel channels. Mass transfer and heat transfer are strongly correlated with the pressure loss. For reasons of energy demand, the catalyst form for a given process is chosen to combine the required mass transport and heat transport with the lowest pressure loss. However, it should be borne in mind that the flow into the fixed-bed reactor (Fig. 1) is generally achieved by means of a feed pipe and a distribution hood. These must therefore be constructed so that the fixed bed or tube bundle is uniformly traversed, and the gas residence time in each tube or each flow filament of the fixed bed is the same. This requirement can always be met simply if the pressure loss in the fixed bed or tube bundle is substantially greater than in the entrance hood. In this case it need only be ensured that the fixed bed is packed so uniformly that no flow bypass is formed or, in the case of a multitube reactor, the pressure loss is equalized in all the individual tubes of the bundle. Because the pressure loss increases with the square of the flow velocity, a uniform distribution of the flow then occurs automatically.

Obtaining a uniform flow distribution is substantially more difficult if the pressure loss of the fixed bed is small. This holds in particular for monolith reactors with straight, laminarly traversed channels (see Section 2.3).

The Hagen – Poiseuille equation is used to calculate the pressure loss in laminarly traversed monolith channels

$$\Delta p = \frac{32\eta Z_L v_G}{d_h^2} \tag{2.1}$$

The pressure loss of packed tubes can be described either by means of a pressure loss coefficient and the pressure drop equation

$$\Delta p = \zeta \cdot \frac{\varrho}{2} \cdot v_G^2 \tag{2.2}$$

or by the Ergun equation:

Figure 7. Behavior of the dimensionless heat-transfer and mass-transfer coefficients over the dimensionless tube length $Nu = \alpha_W \cdot d_h/\lambda_G$, $Sh = k_G \cdot d_h/D$

$$\Delta p = f_1 v_G + f_2 v_G^2 \tag{2.3}$$

where for spherical packings:

$$f_1 = 150 \cdot \eta \cdot \frac{(1-\varepsilon)^2}{\varepsilon^3 \cdot d_p^2} \tag{2.4}$$

$$f_2 = 1.75 \cdot \varrho \cdot \frac{(1-\varepsilon)}{\varepsilon^3 \cdot d_p} \tag{2.5}$$

Thus the pressure drop depends very strongly on the void fraction ε of the packing. Of the standard forms for packed catalysts, hollow cylinders of thin wall thickness ($\varepsilon \approx 0.6-0.8$) are therefore preferred to spheres ($\varepsilon \approx 0.37-0.4$) and solid cylinders ($\varepsilon \approx 0.35$).

The strong dependence of the pressure loss on the void fraction underlines the importance of packing catalyst beds carefully to avoid bypass flow due to local variations in the packing density. For the same reason the tubes of multitubular reactors for highly exothermic, selectivity-sensitive reactions are often filled uniformly by means of special devices and if necessary individually compensated for pressure loss.

The pressure loss coefficient ζ (Eq. 2.2) can be determined for typical packing forms, for example, according to [9].

2.3. Heat Transport Transverse to the Flow Direction

With nonadiabatic reaction control, heat must be transported perpendicular to the flow direction through the fixed bed to the heat exchange surfaces. At the usual mass flow rates of $G_z = 1\,\mathrm{kg\,m^{-2}\,s^{-1}}$, this heat transport takes place mainly by convection, i.e., the fixed bed must be constructed so that flow components transverse to the main flow direction occur locally. Monolith structures with straight parallel channels are thus unsuitable for nonadiabatic reaction control.

In catalyst packings transverse flow components are automatically established as a result of the nonuniform arrangement and the twisted flow around the pellets. Hollow and full cylinders with a length-to-diameter ratio of 1 to 3 are particularly effective in this respect.

Despite the fact that radial heat transport in the form of twisted flow takes place mainly by convection, it is formally described by means of a so-called effective thermal conductivity λ_r transverse to the flow direction.

In addition to heat transport through the fixed bed perpendicular to the main flow direction, the heat transport at the boundary between the fixed bed and heat exchange surface is also decisive for the heat exchange. The latter heat transport is generally described by a wall heat-transfer coefficient α_W, in which the complex interplay between convective flow at the tube wall and conduction transport by contact between the fixed bed and the heat exchange surface is described in overall terms. Heat transport in packed tubes has been investigated and discussed in detail [4], [10]. However, the correlations for α_W and λ_r given in the literature do not adequately take account of the actual velocity distribution in packed tubes. Plug flow was generally assumed, although the actual velocity profile is nonuniform with a pronounced slip at the wall. This is due to the fact that the pellets make only point contact with the wall, whereas they overlap and cross over one another inside the packing, thereby reducing the free volume and hence the velocity. The conditions for a spherical packing are illustrated schematically in Figure 8. The radially varying empty space distribution and velocity distribution must be taken into account in detailed reactor calculations, as well as in the determination of accurate heat-transport parameters [12], [13].

Existing correlation equations for calculating the heat-transport parameters were obtained from heating or cooling experiments without reactions and assuming plug flow; they therefore permit only a semiquantitative evaluation. However, this is adequate for qualitative comparison of catalyst structures.

Figure 8. Radial distribution of the void fraction and axial flow velocity in a tube packed with spheres

2.4. Comparison and Evaluation of Different Catalyst Forms

The choice of a suitable catalyst form is always an optimization problem that can be completely specified only for a specific process. Even then, however, weighting the performance function is not easy since, for example, small pressure losses, uniform flow through the reactor, and good mass- and heat-transfer properties generally represent opposing requirements. The following assessment is therefore only a rough guide.

2.4.1. Catalyst Forms for Adiabatic Operation

Decisive parameters for adiabatic operation include:

1) The active catalyst surface available per unit reactor volume
2) The quality of the mass and heat transfer between the flowing gas and the active catalyst surface
3) The flow pressure loss
4) The uniformity of the flow through the reactor and thus the degree of utilization of the fixed bed

The major proportion of the active catalyst surface is located in the interior of the porous catalyst structure. However, if it is assumed that, in the case of sufficiently fast reactions, the reaction site is restricted to a thin layer underneath the external surface, then the active catalyst surface area can be taken as proportional to the specific external catalyst surface area a_{p}. If the uniform distribution of the flow entering the fixed bed is regarded as a separate problem, then for given kinetic conditions the evaluation may be restricted to three parameters: specific external surface area a_{p}, gas – solid mass-transfer coefficient k_{G}, and the flow pressure loss. The evaluation becomes particularly simple if, with a single dominant reaction, the external gas – solid mass transfer limits the reaction, since in this case the specific reaction kinetics have no influence. The relationships for a concentration c of a key component A and a simple reaction A + ... → products are outlined in [2.11]. Assuming mass-transfer limitation, the material balance for the key component along the flow path is

$$\varepsilon \cdot v_{\mathrm{G}} \cdot \frac{\partial c}{\partial z} = -k_{\mathrm{G}} \cdot a_{\mathrm{p}} \cdot c \tag{2.6}$$

If the reaction has a conversion of 99 %, i.e., an outflow concentration of 1 % of the inflow concentration, the length of the fixed bed Z_{L} is, by integration,

$$Z_{\mathrm{L}} = -\frac{\ln 0.01 \cdot \varepsilon \cdot v_{\mathrm{G}}}{k_{\mathrm{G}} \cdot a_{\mathrm{p}}} = \frac{4.6 \cdot \varepsilon \cdot v_{\mathrm{G}}}{k_{\mathrm{G}} \cdot a_{\mathrm{p}}} \tag{2.7}$$

For the required reactor volume V_{R} with the cross-sectional area A:

$$V_{\mathrm{R}} = Z_{\mathrm{L}} \cdot A = 4.6 \cdot \frac{\dot{V}}{k_{\mathrm{G}} \cdot a_{\mathrm{p}}} \tag{2.8}$$

Correlations for k_{G} can be found in [3], [4]. The computation is particularly simple for straight, laminarly traversed channels. The asymptotic limiting value given in Table 1 (Section 2.1) for the square channel

$$Sh = \frac{k_{\mathrm{G}} \cdot d_{\mathrm{h}}}{D} \approx 3 \tag{2.9}$$

gives, with $a_{\mathrm{P}} = \frac{4}{d_{\mathrm{h}} \cdot \varepsilon}$,

$$k_{\mathrm{G}} \cdot a_{\mathrm{p}} \approx \frac{12D}{d_{\mathrm{h}}^2 \cdot \varepsilon} \tag{2.10}$$

and

$$V_{\mathrm{R}} = 0.38 \frac{\dot{V} \cdot d_{\mathrm{h}}^2 \cdot \varepsilon}{D} \tag{2.11}$$

If Equation (2.1) is used for the pressure loss, then for the laminarly traversed monolith channel, from Equations (2.7) and (2.10)

$$\Delta p = \frac{12.28 \cdot \eta}{D} \cdot v_{\mathrm{G}}^2 \cdot \varepsilon^2 \tag{2.12}$$

Using the above equations, reactor variants for catalytic off-gas purification with a given volume flow $\dot{V}$ were calculated in [11]. The result is shown in Figure 9. The pressure drop of the fixed bed over the required reactor length is plotted; the curve parameter is the hydraulic diameter d_{h} of the monolith channel or packing body for different empty-tube gas velocities $v_{\mathrm{e}} = \varepsilon \cdot v_{\mathrm{G}}$. According to Equation (2.11) the required fixed bed volume V_{R} with square monolith catalysts and a given throughput $\dot{V}$ depends only on d_{h}, whereas the geometric arrangement (small bed cross section A and long bed length Z_{L}, or large bed cross section and short bed) has no influence on V_{R}. However, the bed cross-sectional area A for a given gas throughput $\dot{V}$ determines via

$$\dot{V} = A \cdot v_{\mathrm{G}} \cdot \varepsilon \tag{2.13}$$

the interparticle velocity v_{G}, and according to Equation (2.12) this then appears as a quadratic term in the pressure loss.

In conclusion, a minimum catalyst volume with minimum pressure loss is obtained by using a very flat bed with a large flow cross-sectional area A and small hydraulic channel diameter or particle diameter d_{h}. This result applies in general to all catalyst forms. The main difficulty with this arrangement is the uniform distribution of the flow velocity. Figure 9 shows the improvement in pressure loss that can be achieved by channel monoliths as compared to spherical packings. Other catalyst forms such as Raschig

rings or corrugated-plate packets lie between these boundary curves.

2.4.2. Catalyst Forms for Isothermal Operation

In addition to the previously discussed quantities, the lateral heat-transport parameters of the fixed bed are further decisive parameters in isothermal reaction control. As shown in Section 2.3, heat transport can be characterized by the effective thermal conductivity perpendicular to the main flow direction λ_r and the wall heat transfer coefficient α_W. Both quantities are strongly dependent on the filling or packing form. Since transport in the industrially interesting region mainly occurs by convection, they are approximately proportional to the mass throughput.

For the purposes of overall comparison, the corresponding characteristic parameters are given in Figure 10 for some industrially important filling and packing forms in a tube of 50 mm internal diameter with a mass-flow velocity of $G_z = 1\ \mathrm{kg\,m^{-2}\,s^{-1}}$.

The dimensions of the packing bodies were chosen so that their specific external surface area a_p is ca. 500 $\mathrm{m^2/m^3}$. Under these conditions hollow, thin-walled cylinders have clear advantages over other packing forms, exhibiting the lowest pressure loss and the highest thermal conductivity. Only as regards wall heat transfer are they inferior to spheres or cylinders. However, good wall heat transfer is apparently less decisive from a reaction engineering viewpoint than good radial thermal conductivity, since the former can be compensated by an appropriate temperature profile of the heat-transfer medium, whereas the radial thermal conductivity directly influences the uniformity of the reaction conditions over the tube cross section. On the other hand, solid cylinders with a large length-to-diameter ratio have good heat transport values, but at the cost of a very high pressure loss.

Despite its poor heat transport properties, a monolith with straight, parallel channels, such as used for automobile exhaust control, is included in the comparison.

Monolith forms have very high specific surfaces combined with a very low pressure loss. Crossed corrugated structures are considerably more favorable for isothermal reaction control. They have a very high radial thermal conductivity that is almost independent of the specific surface area; the latter can be varied over a wide range by means of the channel dimensions. The catalyst of a reaction tube can thus be structured so that wide packings of small specific surface area can be used in the region of the main reaction zone, while packings of increasingly narrower structure, i.e., large specific surface area, are used downstream. In this way a more uniform reaction rate and temperature profile can be achieved over the tube length (see Section 4.3.3).

However, it must be remembered that with crossed corrugated structures, convective radial heat transport occurs only in one plane perpendicular to the main flow direction. In addition, the flow behavior in tubes of circular cross section is rather nonuniform over the circumference, which is why it is advantageous to arrange short packing sections in series, each section being displaced by 90 °. The heat transport parameters in Figure 10 were determined for structures arranged in this way.

A general problem in the use of monolith structures in reaction tubes is incomplete wall contact. Since individual tubes of multitubular reactors always have a diameter tolerance of ca. 1 mm and interlocking of the structure with the tube wall must be avoided, the bypass of flow at the wall is even greater than with random packings. Up to now there have been no specific investigations of the magnitude and effects of this phenomenon.

Figure 10. Specific outer surface area a_p, void fraction ε, effective radial heat conductivity λ_r, wall heat-transfer coefficient α_W, and pressure drop Δ_p for different packings in a tube of 50 mm internal diameter and an air mass-flow velocity $G_z = 1\ \mathrm{kg\,m^{-2}\,s^{-1}}$ at ambient conditions

3. Adiabatic Reaction Control

Adiabatic fixed-bed reactors are the oldest fixed-bed reactor configuration. In the simplest case they consist of a cylindrical jacket in which the catalyst is loosely packed on a screen and is traversed in the axial direction (Fig. 11 A). To avoid catalyst abrasion by partial fluidization, catalyst packings are always traversed from top to bottom. If fixed beds composed of monolith catalyst sections are used, the flow direction is arbitrary.

As discussed in Section 2.4.1, the requirement for a low pressure loss leads to a fixed bed of large diameter and low height (Fig. 11 B). Such an arrangement (disk concept) is used particularly when very short residence times, followed by direct quenching of the reaction, are required. Examples include ammonia oxidation in nitric acid production (→ Nitric Acid, Nitrous Acid, and Nitrogen Oxides, Chap. 1.3.) and oxidative dehydrogenation on silver catalysts (e.g., synthesis of formaldehyde by dehydrogenation of methanol, → Formaldehyde, Chap. 4.1., → Formaldehyde, Chap. 4.2.). In the first case the "fixed bed" consists of several layers of platinum wire gauzes, and in the second case, of a porous silver layer several centimeters in height. The bed diameters can be up to several meters.

On account of the difficulties involved with obtaining uniform flow as well as for structural reasons, the disk concept is limited to small catalyst volumes. The radial flow concept (Fig. 11 C) is used where large amounts of catalyst are involved. The catalyst packing is accommodated in the space between two concentric screen rings or perforated plate rings, and is traversed radi-

ally, either from the inside to the outside or from the outside to the inside. This design is particularly suitable for large catalyst volumes as well as for operation at elevated pressure, since at moderate reactor diameters the catalyst volume can be varied over a wide range by altering the reactor length, without affecting the flow-through length of the packing.

Figure 11. Main design concepts for adiabatic reactors
A) Adiabatic packed-bed reactor; B) Disk reactor;
C) Radial-flow reactor

A critical feature of packed radial-flow reactors is the shape of the upper bed closure. A simple horizontal covering is not practicable since a gap through which unreacted gas can pass is then formed due to the unavoidable settling of the packing. The arrangement shown in Figure 12 has proved effective since it produces mixed axial and radial flow through the bed in the upper bed closure. The required geometrical shape must be determined by simulation of the local two-dimensional flow through the packing [14].

Figure 12. Upper bed closure in a radial-flow reactor [14]

Figure 13. Reaction chamber for removal of nitrogen oxides from power station flue gas [15]

Figure 14. Velocity distribution in an industrially housed automobile catalyst [11]

The advantages of monolith catalysts with straight, parallel channels for adiabatic reactors have already been referred to in Section 2.4.1. Since monolith catalysts are usually produced with a rectangular cross section, the fixed bed is constructed by arranging these individual monoliths in rows in the form of a large "box". Conventional DENOX reactors for removing NO_x from power station flue gases are therefore designed as rectangular chambers (Fig. 13). The catalyst is often arranged in the form of several layers in series, the spaces between the individual layers permitting cross-mixing, so that the influence of nonuniform flow as well as any possible local blockage of the next layer can be compensated to some extent.

Reference is made in Section 2.2 to the importance of uniform flow into and through adiabatic fixed-bed reactors. This is not easy to achieve, particularly with low-pressure-loss monolith reactors, and requires a careful design of the inflow hood. On account of the low pressure loss, unfavorable flow conditions in the outflow hood may also affect the flow behavior through the catalyst bed.

Figure 14 shows the velocity distribution in front of the monolith inlet for an industrially housed automobile catalyst [11]. Since the flow cannot follow the sudden widening of the inlet funnel, one third of the total cross section is traversed at a velocity that is roughly three times the mean velocity. It can be estimated that, with uniform flow through the catalyst, half the catalyst volume would be sufficient for the same mean conversion. Also, bends in the feedpipe can lead to swirl-type components and thus contribute to nonuniform flow.

Purely adiabatic fixed-bed reactors are used mainly for reactions with a small heat of reaction. Such reactions are primarily involved in gas purification, in which small amounts of interfering components are converted to noninterfering compounds. The chambers used to remove NO_x from power station flue gases, with a catalyst volume of more than $1000\,m^3$, are the largest adiabatic reactors, and the exhaust catalysts for internal combustion engines, with a catalyst volume of ca. 1 L, the smallest. Typical chemical applications include the methanation of CO and CO_2 residues in NH_3 synthesis gas, as well as the hydrogenation of small amounts of unsaturated compounds in hydrocarbon streams. The latter case requires accurate monitoring and regulation when hydrogen is in excess, in order to prevent complete methanation due to an uncontrolled rise in temperature, a so-called runaway (see Chap. 6).

4. Reaction Control with Supply or Removal of Heat in the Reactor

4.1. Introduction

In the majority of fixed-bed reactors for industrial synthesis reactions, direct or indirect supply or removal of heat in the catalyst bed is utilized to adapt the temperature profile over the flow path as far as possible to the requirements of an optimal reaction pathway. Here a clear developmental trend can be observed, which is illustrated schematically in Figure 15.

Development started with the adiabatic reactor (Fig. 15 A), which on account of the adiabatic

Figure 15. Development of fixed-bed reactors
A) Single-bed adiabatic packed-bed reactor; B) Adiabatic reactor with interstage gas feed (ICI concept); C) Multibed adiabatic fixed-bed reactor with interstage heat exchange; D) Multitubular fixed-bed reactor; E) Multitubular fixed-bed reactor with two cooling circuits and nonisothermal cooling temperature (the temperature profile shown is for a strongly exothermic reaction)

temperature change could only be operated to give a limited conversion. Higher conversions were achieved at the same mean temperature level when several adiabatic stages were introduced, with intermediate heating or cooling after each stage. The simplest form involves injecting hot or cold gas between the stages (Fig. 15 B). For a constant tube diameter, the main disadvantages of this temperature control strategy are cross-sectional loading, which increases from stage to stage, and the mixing of hot and cold streams, which is energetically unfavorable. The composition is changed by injection, which can have a positive or negative effect on the desired reaction.

The next development was the replacement of injection cooling by interstage heat exchangers, through which the required or released heat of reaction is supplied or removed (Fig. 15 C).

The development of reactors in which the heat-exchange surfaces are integrated in the fixed bed to supply or remove the heat of reaction as close as possible to the reaction site occurred in parallel with the development of multistage adiabatic reactors with intermediate heating or cooling. The multitubular fixed-bed reactor (Fig. 15 D) constitutes the oldest and still predominant representative of this class of fixed-bed reactors. Here the catalyst packing is located in the individual tubes of the tube bundle. The heat-transfer medium is circulated around the

tube bundle and through an external heat exchanger, in which the heat of reaction is supplied or removed. Whereas with endothermic reactions, circulating gas can be used as heat-transfer medium, for strongly exothermic reactions exclusively liquid or boiling heat-transfer media are used. Only in this way can the catalyst temperature (e.g., in the case of partial oxidations) be held in the narrow temperature range necessary for selective reaction control.

Initially, the integration of heat exchange in the fixed bed was utilized to ensure as isothermal a reaction control as possible, which is why reactors of the type shown in Figure 15 D are also commonly termed "isothermal reactors". They are characterized by reaction tubes of 20 – 80 mm internal diameter and a carefully designed flow control of the liquid heat-transfer medium, with largely constant heat-transfer conditions throughout the tube bundle and maximum temperature changes of the heat-transfer medium in the tube bundle of a few degrees.

The latest concepts are aimed at establishing a freely selectable (within limits) optimum temperature profile over the tube length. This requires complex heat-transfer medium control with several sections and temperature levels (Fig. 15 E).

The stimulus for the developments outlined in Figure 15 was the need for total raw material utilization as regards both mass and energy. This involves as main criteria the yield of primary end products (maximum), the yield of byproducts that must be removed and eliminated (minimum), the thermal energy consumption or recovery, and the mechanical energy requirements (gas compression, circulation of heat-transfer medium). In addition to the running costs, which are determined by the above criteria, the investment costs are decisive in an investment decision, and naturally rise sharply with increasing complexity of the reaction cycle.

On account of cost degression the projected plant size and the subsequent degree of utilization as well as the technological sophistication are decisive in calculating the product price. Several of the fixed-bed reactor variants illustrated in Figure 15 can, depending on the location of the production site and the estimated output, be used for the same process. For example, multistage adiabatic reaction systems with intermediate superheated steam feed, multitubular reactors with circulating gas heating, and strictly isothermal designs with multitubular reactors heated with molten salt are currently used for the endothermic synthesis of styrene from ethylbenzene. Also, exothermic, equilibrium-limited reactions such as methanol synthesis are carried out in multistage adiabatic reactors with interstage cooling as well as in multitubular reactors. Overall, however, there is a trend towards the more highly integrated designs, which will accelerate with rising energy and raw material prices. Adiabatic multistage designs and reactors with heat exchange integrated in the fixed bed are discussed in the following sections. Autothermal reaction control, in which the heat of reaction of moderately exothermic reactions is utilized to heat the incoming feedstock, is discussed separately in Chapter 5.

4.2. Adiabatic Multistage Reactors with Interstage Heat Transfer

Adiabatic multistage fixed-bed reactors with intermediate cooling or heating are nowadays used particularly where the reaction proceeds selectively to give a single product but is limited by the equilibrium conditions. Intermediate cooling or heating is used to displace the gas temperature in the direction of higher equilibrium conversion. Typical examples include the synthesis of ammonia, sulfur trioxide, and methanol. In these exothermic reactions the equilibrium conversion to the target product decreases with increasing temperature, as shown in Figure 16 A. For a given conversion x a temperature can therefore be found at which the reaction rate, with respect to the target product, becomes a maximum. This temperature must be below the equilibrium temperature but not so low that the reaction becomes too slow for kinetic reasons. The points obtained in this way can be joined to form a maximum reaction rate curve (Fig. 16 B).

Since, in the case of adiabatic reaction control the temperature increases linearly with the achieved conversion Δx according to the equation,

$$\Delta T = -\frac{\Delta h_{\mathrm{R}} \cdot c_0}{\varrho_{\mathrm{G}} \cdot c_{\mathrm{pG}}} \cdot \Delta x \tag{4.1}$$

Figure 16. Equilibrium limitation of exothermic reactions
A) Equilibrium conversion as a function of temperature; B) Optimum reaction rate curve; C) Improvement of conversion by interstage cooling

each adiabatic reaction pathway of an exothermic reaction lies on a straight line of gradient $\Delta T/\Delta x$ (see Fig. 16 A).

A practicable reaction pathway for a multistage adiabatic reaction can thus be derived from Figure 16 by joining straight-line sections for the adiabatic reaction to vertical lines for the temperature reduction due to indirect intermediate cooling (Fig. 16 C).

The kinetically optimum reaction pathway with the smallest required catalyst volume results when the trajectory follows, in a large number of small steps, the line of maximum reaction rate. In practice, the apparatus and equipment expenditure involved in a large number of stages must be weighed up against the savings in catalyst. Conventional multistage reactors for this class of reaction therefore have three to five stages. Figure 17 shows the layout of an ammonia synthesis reactor designed on this basis. For structural reasons the heat exchanger is incorporated between the inflow and outflow in the lowest part of the pressure casing. The reaction gas then flows upward in the annular gap between the pressure casing and the fixed beds, whereby it is further heated and at the same time protects the pressure-bearing structural components against excessively high fixed-bed temperatures. The three adiabatic fixed-beds are traversed from top to bottom, part of the heat of reaction being utilized to generate steam in the two intermediate heat exchangers. To start up the cold reactor, hot gas must be added to the uppermost bed, for example through an external start-up preheater.

Industrial adiabatic multistage reactors often differ in many details from Figure 17, although they are of a comparable basic design. For example, radially instead of axially traversed beds can achieve a smaller pressure loss with a more favorable structural arrangement; heat exchange with the cold feedstock can be effected by heat exchange surfaces integrated in the first catalyst bed; or a cold gas quench can be used to achieve additional temperature regulation.

Modern, adiabatic multistage reactors may thus become so complex that the question arises whether a multitubular design according to Figure 15 D or E does not represent the more favorable alternative. The required heat-exchange surface area in the case where heat exchange is integrated in the fixed bed is smaller than in the case of free gas flow on account of the positive effect of the catalyst packing. Furthermore, it does not involve any additional pressure loss, and the optimum reaction rate curve (Fig. 16 B) can be better approximated by controlling the cooling temperature profile (see Section 4.3.2.) than by a stepwise temperature reduction.

On the other hand, a multistage arrangement may be considered for structural, operating technology, or kinetic reasons in the following cases:

1) If, in the case of large single-train plants, subdivision into several individual items of apparatus is necessary for reasons of transport or construction
2) If a catalyst must be replaced in individual stages at different times on account of different catalyst compositions and/or aging
3) If a gradual addition of a reactant has kinetic advantages compared to the total addition to the feed (here a suitably designed intermediate heat exchanger ensures a uniform dis-

Figure 17. Schematic of a multistage reactor for ammonia synthesis

tribution and mixing with the reaction gas stream)

4) If the intermediate stages are used to extract a limiting product in the case of equilibrium-limited reactions; an example is the intermediate absorption of SO_3 before the last stage of the SO_3 synthesis
5) With reaction temperatures above 300 °C intermediate cooling can be performed directly with boiling water, whereas in a fixed bed a high-temperature heat-transfer medium must be used as coolant (see Section 4.3.1)

4.3. Reactors with Heat Exchange Integrated in the Fixed Bed

The aim of reaction control with heat exchange integrated in the fixed bed using a circulating heat-transfer medium is to maintain the catalyst temperature in a narrow optimum range under all operating conditions. With strongly exothermic successive reactions, such as partial oxidations and partial hydrogenations, on account of the danger of a runaway reaction (see Section 6.2) this requirement can be met only if

1) The temperature of the heat-transfer medium is close to the desired catalyst temperature
2) Large heat- exchange surfaces are available per unit catalyst volume
3) A sufficiently large mass flow velocity of the reaction gases ensures good heat transport from the packing to the heat-exchange surface

With exothermic equilibrium reactions and endothermic reactions these requirements are less stringent since these reactions cannot runaway, although here too it is beginning to be recognized that a tight and uniform temperature control over the reactor cross section is advantageous.

4.3.1. Heat Transfer Media for Fixed-Bed Reactors

The first of the above requirements presupposes an assortment of heat-transfer media that covers the whole temperature range of interest for gas-phase reactions in fixed-bed reactors. It is convenient to distinguish between gaseous, liquid, and vaporizing heat-transfer media. Gaseous heat-transfer media in the form of hot flue gases are used in the temperature range above 500 °C exclusively to supply heat for endothermic reactions.

Conversely, vaporizing heat-transfer media are used exclusively to remove heat from exothermic reactions. Whereas formerly petroleum fractions such as kerosene (e.g., in ethylene

oxide synthesis) were more widely used, they have now been largely replaced by boiling water on account of their flammability, lower heat of vaporization, and the need to produce steam in a downstream condenser/heat exchanger. Depending on the saturated vapor pressure, the temperature range from 100 to 310 °C (100 bar) can be covered with boiling water. In this range it is the preferred heat-transfer medium for evaporative cooling if an isothermal cooling temperature is required.

Locally variable cooling temperature profiles can be established most easily with liquid heat-transfer media that do not vaporize in the intended operating range. In order to avoid cavitation, pressurized water should be used only up to ca. 220 °C; heat-transfer oils cover the temperature range up to 300 °C, while above this temperature salt melts are now used exclusively in reaction technology [16]. Compared to heat-transfer oils they have the advantage that they are incombustible and stable, although they have the disadvantage that they solidify at about 200 °C (nitrate melts) or 400 °C (carbonate melts). The temperature ranges of possible heat-transfer media are compared in Figure 18. In addition to the thermal stability, the energy $\dot{N}$ per unit amount of transported heat $\dot{Q}$ required to circulate a heat-transfer medium is an important criterion of choice.

The following equation has been derived for the evaluation of heat-transfer media without phase change [26]:

$$\frac{\frac{\dot{Q}}{\Delta T_c}}{\dot{N}^{0.36}} \sim \frac{\varrho^{0.73} \cdot c_p}{\eta^{0.09}} \tag{4.2}$$

where $\dot{Q}$ is the heat flow transferred by the heat-transfer medium while its temperature increases by exactly ΔT_c, $\dot{N}$ is the required pump power, and ϱ, c_p, and η are the density, specific heat capacity, and viscosity of the heat-transfer medium. For liquid heat-transfer media, the equation is derived from the pressure drop in a turbulently traversed, hydraulically smooth pipe. It is practical to solve Equation (4.2) for the pump power:

$$\dot{N} \sim \left[\frac{\dot{Q}}{\Delta T_c}\right]^{2.75} \cdot \frac{\eta^{0.25}}{c_p^{2.75} \cdot \varrho^2} \tag{4.3}$$

Thus the required power varies as almost the third power of $\dot{Q}/\Delta T_c$. The component $\eta^{0.25}/c_p^{2.75} \cdot \varrho^2$, which depends only on the physical properties of the heat-transfer medium, is plotted as a function of temperature in Figure 19. This shows the exceptional heat-transfer properties of water that result from its density and, in particular, its high specific heat, as well as the properties of gases (air) and vapors (water vapor), which are about seven orders of magnitude worse. Common heat-transfer oils and salt melts (sodium nitrate) lie close together, but about an order of magnitude above water. The poor performance of molten sodium compared to heat-transfer oils and salt melts is noteworthy.

To test Equation 4.3 on a more realistic example of the cooling of a multitubular reactor, a quadratic tube bundle (cross section 1.5×1.5 m) with fourfold passage of the coolant was designed by using detailed equations for pressure drop and heat transfer [27] for various heat-transfer media. The heat release of 1650 kW in 1591 (37×43) tubes of 30 mm external diameter and 4 m length corresponds to the conditions in a partial oxidation reaction. A temperature rise between feed and outlet of $\Delta T_c = 5$ K was assumed for the heat-transfer medium (additionally 150 K for air and water vapor). Table 2 lists as results the required pump power $\dot{N}$, the pressure drop in the cooling circuit Δp (whereby $p = 1$ bar exit pressure was assumed for water vapor and air), and the excess temperature of the reactor wall above the heat-transfer medium temperature ΔT_W, assuming constant wall temperature along the length of the tube. It was shown that the results of these more precise design equations for the liquid heat-transfer media can be correlated with the equation

$$\dot{N} = 7800 \left[\frac{\dot{Q}}{\Delta T_c}\right]^{2.73} \frac{\eta^{0.27}}{c_p^{2.73} \cdot \varrho^2} \tag{4.4}$$

This represents a good confirmation of Equation (4.3).

Water is thus the ideal heat-transfer medium within its temperature range. For higher temperatures molten salts have increasingly replaced the previously more commonly used heat-transfer oils. Salt melts cover a larger temperature range and have the particular advantage over oils that they are incombustible. The potential danger of a relatively large amount of hot salt melt obviously exists, but is reliably dealt with by experienced reactor construction companies. Special

Air		0.456×10^3	0.341	12.29	150

nitrate melts (HITEC) can be used in the temperature range 200 – 500 °C. Gradual decomposition begins above this temperature, which can accelerate violently above 600 °C. Access of organic components to the melt (nitrate decomposition) and of water (steam explosion) must be excluded [16]. New salt melts, for example, based on carbonates, are being developed for the temperature range 400 – 800 °C. In this case it is not so much the thermal stability of the molten salt but rather the corrosion of the reactor materials that presents problems.

Gases are the only heat transfer media usable over the entire temperature range, but because of their low density they have an unfavorable heat transport behavior (Fig. 19). They are therefore used exclusively as flue gases to supply heat at high temperatures. However, large temperature differences between the heat-transfer medium and the reactor wall, with possible adverse effects on the uniformity of the heat supply, must then be accepted.

4.3.2. Reactor Designs

As with adiabatic reactors, a principal task of reactor development is to produce uniform reaction conditions over the whole reactor and maintain such conditions during the entire operating time. This involves the conditions in the catalyst packing (residence time, catalyst concentration and activity, heat transport) and in the heat-transfer medium circuit (throughput, temperature, heat transfer). When liquid or vaporizing heat-transfer media are used, the heat-transfer coefficients are usually one order of magnitude greater than those on the catalyst side, which facilitates the task as regards the heat-transfer medium. On the other hand, with strongly exothermic, selectivity-sensitive reactions (especially partial oxidations), a temperature constancy of the heat-transfer medium of ca. 1 °C is often required. This leads to a high energy requirement for circulation (according to Eq. 4.4) and necessitates extremely careful design and control of the heat-transfer medium circuit.

Tubular reactors of the type shown in Figure 15 D have been in use longest and have been furthest developed. In the case of a vaporizing heat-transfer medium an arrangement as shown in Figure 20 is generally chosen, in which the liquid heat-transfer medium surrounds the stationary tube bundle. The rising vapor bubbles escape through the ascending pipe into a vapor drum, where they are separated from the liquid. A circulation flow is established due to the difference in density in the downpipe (pure liquid) and in the reactor jacket, which means that circulating pumps are generally not required. The heat-transfer medium temperature is regulated via the saturated vapor valve. Specific details of this regulation are discussed in Section 6.6.

Figure 20. Multitubular reactor with boiling water cooling

If uniform supply and removal of heat-transfer medium via annular channels is ensured, this arrangement provides reliable isothermal reaction control. Since a steam cushion can form under the upper tube floor, the active catalyst layer should begin only at a deeper level.

Apart from the type of multitubular reactor shown in Figure 20, other multitubular reactors are sometimes used in which the catalyst bed is arranged around the tubes and the heat-transfer medium flows through the tubes (Fig. 21 B). An interesting new development has been introduced by Linde (Fig. 21 A): the tube bundle is composed of counterwound spirals in which upwardly flowing water is evaporated. The tubes run into a vertical vapor drum located at the reactor head. The tube bundle is connected to a central downpipe at the bottom so that, as in the arrangement in Figure 20, a natural circula-

tion of the evaporating water is established. Advantages in construction and in the heat transfer from the reaction gas to the tubes of the bundle are claimed for this design [28].

Figure 21. A) Design concept of the Linde isothermal reactor for methanol synthesis; B) Cut through the tube bundle surrounded by catalyst pellets (from [31])

Circulation systems with parallel and crossed cocurrent or countercurrent flow of the heat-transfer medium (Fig. 22) are commonly employed for liquid heat-transfer media. The main part of the heat-transfer medium is generally circulated with a high-capacity pump in order to achieve uniform heat-exchange conditions, while a partial stream is passed through a heat exchanger for supplying or removing the heat of reaction. The desired heat-transfer medium temperature is attained by regulating this partial stream. With exothermic reactions the heat exchanger is normally a steam generator which produces saturated steam at a pressure corresponding to a boiling point of 30 – 80 °C below the maximum cooling temperature.

A superheater fed with a further partial stream of the heat-transfer medium can if necessary be connected downstream of the steam generator. The arrangement with separate external units, shown schematically in Figure 22 has structural and maintenance advantages over a common arrangement in the tube-free interior of the reactor [29].

Apparatus construction companies specializing in these reactors have developed a detailed and comprehensive know-how as regards flow control of the heat-transfer medium [30]. This concerns the uniform supply and removal of the heat-transfer medium, which generally takes place via external annular channels, as well as the flow control within the reactor. Here a distinction is made between parallel flow control and crossed flow control. Parallel flow control (Fig. 22 B) is achieved by two rectifier plates with narrow bores. On account of the pressure loss through the bores suitably arranged over the reactor radius, a uniform flow profile is produced over the cross section with uniform heat removal conditions between the distributor plates. The advantage of this arrangement is that the whole reactor can be equipped with tubes.

However, due to the nonuniform flow conditions in the inflow and outflow region of the heat-transfer medium, only the region between the distributor plates should be filled with active catalyst. Heat transfer is low because of the parallel flow of the heat transfer medium, and the pressure loss in the distributor plates does not contribute to improving the heat transport. For this reason this arrangement is preferably used for reactions with a moderate heat of reaction.

Figure 22. Heat-transfer medium control in tube-bundle fixed-bed reactors
A) Cross flow; B) Parallel flow

Figure 23. Influence of the coolant flow direction and flow velocity v_s on the reaction temperature profile
A) Isothermal; B) Cocurrent flow; C) Countercurrent flow

In reactions with a large heat of reaction, especially partial oxidations, transverse flow control is more widely used, generally in a radially symmetrical arrangement with baffle plates, as illustrated in Figure 22 A. Since the heat removal conditions are poorly defined in the region of the flow deflection, with the change from a transverse stream to a parallel stream and back to a transverse stream, this region should be free of tubes. A difficulty arises from the constant change of the flow cross section in the radial direction. However, this can be alleviated, for example, by providing pressure-relief bores in the baffle plates, increasing in number towards the reactor axis. In this way constant heat-transfer conditions should be achieved over the reactor radius. In summary, ensuring uniform heat transfer conditions as regards the heat-transfer medium thus requires a considerable flow technology know-how. Some publications illustrate the major differences in the behavior of different tube sections that can arise due to an inadequate design and layout of the heat-transfer medium circuit [17–19].

4.3.3. Influencing the Course of the Reaction

The course of the reaction (i.e., the conversion and selectivity or yield) can be decisively influenced by the arrangements made for controlling the heat-transfer medium. The most obvious, although technically most complex solution, is to

arrange different heat-transfer medium circuits so as to achieve a stepwise approximation of an optimum temperature profile. The purposeful utilization of the temperature change of the heat-transfer medium flowing through the reactor is, however, technically simpler, and is discussed here in connection with cocurrent or countercurrent cooling of a fixed-bed reactor involving an exothermic reaction.

Figure 23 shows temperature profiles for three different ways of controlling the cooling stream in a partial oxidation reaction. If the coolant is circulated so fast that its temperature in the reactor scarcely alters, then its flow direction is irrelevant and a temperature profile with a pronounced temperature maximum becomes established; this is typical of strongly exothermic reactions (Fig. 23 A). If the coolant is circulated in cocurrent and its velocity is chosen so that it becomes noticeably hotter over its path, an almost isothermal temperature behavior can be achieved (Fig. 23 B). This is because the reactive gas at the inlet is in contact with the coldest coolant and the cooling temperature rises in step with the consumption of the reactants, so that the reaction rate remains virtually constant over a fairly long section [20–22]. This stabilizing effect of cocurrent cooling has hardly been exploited up to now in industrial reactors. This may be due to the fear that, at the required low flow velocity (in the example of Fig. 23 B, $v_s = 0.01$ m/s), heat transfer will be inadequate and natural convection will occur in the cooling jacket. However, v_s describes the mean coolant velocity parallel to the tube axis. With a cross-cocurrent flow of the coolant, the actual flow velocity may in fact be substantially larger, depending on the number of deflections, with the result that the aforementioned problems do not arise.

Compared to cocurrent flow, countercurrent flow has a markedly destabilizing effect at low flow velocities (Fig. 23 C). Since the incoming reaction mixture in this case is in contact with the warm coolant outflow, the maximum temperature rises to much higher values. Countercurrent cooling can even lead to the occurrence of several stationary states, and in general favors the runaway of a strongly exothermic, irreversible reaction (see Section 6.3). In contrast to heat exchange without a reaction, countercurrent control of the heat-transfer medium in reactors involving exothermic reactions should therefore be chosen only in particular cases.

Figure 24. Influence of the heating agent flow direction on the temperature profile in styrene synthesis

Figure 25. Influence of activity profiles on the temperature profile of a strongly exothermic reaction
A) Catalyst with 66 % activity in the front section of the tube and 100 % activity in the rear section of the tube [23]; B) Linear (broken line) and optimal catalyst activity distribution (full line) for limiting the maximum temperature to 370 °C (simulation result); C) Experimental verification of B [25]

The temperature control of an exothermic equilibrium reaction can constitute such a case. As illustrated in Figure 16 B, the optimum temperature profile should in this case decrease with increasing conversion, i.e., along the tube length. On account of the equilibrium inhibition of the reaction, it is not possible for the reaction to runaway in the front region. Countercurrent flow of the heat-transfer medium is also advantageous for endothermic equilibrium reactions. Figure 24 shows the calculated temperature and concentration profiles with different heating conditions in the synthesis of styrene (dehydrogenation of ethylbenzene). With adiabatic and isothermal reaction control, styrene formation decreases with increasing tube length, whereas it remains roughly constant with countercurrent control.

A significant advantage of nonisothermal control of the heat-transfer medium in cocurrent or countercurrent flow is the saving in circulation energy, since much smaller heat transfer-medium streams must be circulated. Overall, the combination of several heat-transfer medium circuits (Fig. 15 E) and the purposeful utilization of the temperature change of the heat-transfer medium in the reactor offer a wide range of possibilities of establishing optimum temperature profiles for a given reaction, and of counteracting any changes in activity that occur during the operating life of the catalyst by altering the temperature profiles.

A further possibility of influencing the course of the reaction is to use catalysts of different activities over the reactor length. Particularly with strongly exothermic reactions that are liable to runaway, such as partial oxidations, a less active catalyst is occasionally used in the front part of the reactor in order to avoid too high a maximum temperature. Figure 25 A illustrates the use of two catalysts of differing activity in series. The resulting temperature profiles have a typical double-hump shape [23], [24]. This can be avoided if an activity profile is established by using a continuously varying mixture of catalysts with different activities (Fig. 25 B, C) [25]. In these cases the fully active entry region (relative activity 1) is designed so that the temperature rises to a preselected maximum value. In order to maintain the temperature at this value, the activity in the following region is sharply decreased and is then raised to a relative activity of 1 as the reaction rate drops due to the depletion of the reactants. A smooth temperature profile

can be achieved even if the optimized activity profile in Figure 25 B is only approximately realized (Fig. 25 C).

The control of the maximum temperature by using locally differing catalyst activities presents problems if the main reaction zone moves into the region of high catalyst activity due to changes in the operating conditions. For example, in the case of Figures 25 B and C, a decrease in the throughput may already result in reaction runaway in the short, fully active front region. This can be counteracted by reducing the activity of this zone. Catalyst deactivation occurring during operation may have more serious effects. If, for example, the catalyst is poisoned in a front migrating from the entrance to the rear, the main reaction zone finally migrates to the highly active rear catalyst region, which may lead to excessively high temperatures that can no longer be controlled.

In general, influencing the reaction course via control of the cooling stream is more flexible than incorporating catalysts of different activities. Particularly with nonisothermal control of the heat-transfer media, the reaction course can be influenced over a wide range by means of the inflow temperature of the heat-transfer medium as well as by its volumetric flow rate.

5. Autothermal Reaction Control

5.1. Introduction

The expression autothermal reaction control is used with fixed-bed reactors if the heat of reaction is utilized to heat the reactor feed to the ignition temperature of the catalyst. Then, neither addition nor removal of heat occurs during stationary operation of the reactor. It thus follows that autothermal reaction control is restricted to exothermic reactions in which a moderately large amount of heat is produced. As a measure of the heat release, the adiabatic temperature increase ΔT_{ad} is usually used. This characterizes the temperature increase that the reaction mixture would experience at the maximum possible conversion Δx if no heat were released. As already given in Equation (4.1):

$$\Delta T = -\frac{\Delta h_{\mathrm{R}} \cdot c_0}{\varrho_{\mathrm{G}} \cdot c_{\mathrm{pG}}} \cdot \Delta x$$

Figure 26. Reactor circuits for autothermal reaction control with indirect heat exchange
A) External heat exchange; B) Internal heat exchange

If the conversion is not limited by the reaction equilibrium, then $\Delta x = 1$ and ΔT_{ad} depends only on the inflow concentration c_0 of a key component. Autothermal reaction control is used in practice if the adiabatic temperature increase is in the range $20\,\mathrm{K} \leq \Delta T_{\mathrm{ad}} \leq 300\,\mathrm{K}$. Autothermal reaction control can be realized in several ways, the simplest being to couple an adiabatic reactor with a countercurrent heat exchanger in which the hot outflow heats the cold inflow (Fig. 26 A). If the heat exchanger is not to become impracticably large, this arrangement is suitable only for an adiabatic temperature increase $>$ ca. 200 K. If the heat exchange is in-

Figure 27. Autothermal reaction control with direct (regenerative) heat exchange for an irreversible reaction [11]
A) Basic arrangement; B) Local concentration and temperature profiles prior to flow reversal in steady state; C) Variation of outlet temperature with time in steady state

tegrated in the reactor (Fig. 26 B), then a better heat transfer can be achieved inside the catalyst-filled tubes as well as around the tubes as a result of the transverse flow, so that also gases with a somewhat lower adiabatic temperature rise can be reacted autothermally. Overall, however, indirect gas – gas heat exchange is a weakness of this reactor concept.

5.2. Reaction Control with Periodic Flow Reversal

A major improvement was the autothermal reaction control with direct, regenerative heat exchange, developed by Matros et al., in which the catalyst packing simultaneously acts as the regenerative heat exchanger [32–34]. Figure 27 A shows the basic arrangement. After the catalyst fixed bed has been heated to the reaction temperature, for example, with a pilot burner, the cold reaction gas flows into the packing, where it is heated by the hot catalyst packing and then reacts. At the same time the inflow part of the packing is cooled, so that the reaction front migrates into the packing (Fig. 27 B). Before the reaction front has reached the end of the bed, the flow direction is reversed by valves, so that the temperature front moves back again and heats the cooled part of the packing. In this way a periodic steady state is finally established, in which the temperature profile moves up a certain amount in one half cycle, and moves down by the same amount in the next half cycle. The upper and lower ends of the packing each serve as a regenerative heat exchanger, the hot reaction zone being maintained in each case in the interior of the packing.

If the fixed bed is adiabatically insulated, the heat of reaction can leave the reactor only via the outflow. This leads to the saw-toothed course of the outflow temperature T' with time shown in Figure 27 C. From the total energy balance it can easily be seen that the time-average value of the outflow temperature must lie exactly ΔT_{ad} above the inflow temperature. Nevertheless, the temperature peaks shown in Fig. 27 C may considerably exceed this mean value.

The main advantage of this form of reaction control is the very effective regenerative heat exchange in the catalyst packing, which does not require any additional built-in components and permits autothermal reaction of gas mixtures with an adiabatic temperature increase of less

than 20 K. The main application of autothermal reaction control with periodically varying flow direction is catalytic off-gas purification, in particular catalytic oxidation of small amounts of combustible substances in exhaust air [11]. In addition this form of reaction control has been tested by MATROS et al. for equilibriumlimited exothermic reactions such as SO_3, methanol, and ammonia synthesis, and has in some cases been employed on an industrial scale [32–34].

Figure 28. Alternative arrangements for autothermal reactor design with regenerative heat exchange
A) Radial flow concept; B) Multiple-bed arrangement

In addition to the standard variants shown in Figure 27, a number of modifications have been proposed and applied (Fig. 28). For example, the bed shown in Figure 28 A can be designed as a radial flow system, so that the hot region insulates itself, and a multibed arrangement may be used to avoid flushing losses when reversing the flow direction, one bed being backflushed each time (Fig. 28 B). The arrangements of Figure 29 offer an elegant possibility of a valveless, continuous operation with an integrated flushing stage [11]. Analogous to the Ljungström heat exchanger, the rotation of the segmented fixed bed with a stationary inlet, outlet, and flushing segment leads to a periodic change in the direction of flow through the bed, which can be either axial (Fig. 29 A) or radial (Fig. 29 B).

Figure 29. Schematic of flow control with a rotating catalyst bed [11]
A) Axial-flow reactor; B) Radial-flow reactor
The flushing segment is shaded.

5.3. Reactor Behavior

Due to the direct coupling of the reaction with the heat exchange, autothermal reaction control exhibits some specific features as regards reactor behavior that distinguish it from the behavior of conventionally operated fixed-bed reactors. Firstly, the autothermal procedure presupposes the existence of several stationary operating states (see Section 6.3). The "ignited" operating state is the desired state, for only then is so much heat released that the cold inflow can be heated. In the "extinguished" state the reactor cools to the inflow temperature, so that no further detectable conversion takes place. The object of reaction control of autothermal reactors is to prevent extinction of the reaction, but also to limit the rise in the maximum temperature in the reactor due to the positive thermal feedback (see Section 6.3).

With regard to the combined handling of autothermal reaction control with indirect and direct (regenerative) heat exchange, it is convenient to consider the limiting case of a very rapid reversal of the flow direction [11]. For the sake of simplicity the discussion is restricted to a simple, irreversible exothermic reaction. A typical example is the catalytic oxidation of a combustible component in a waste air stream.

Figure 30. Equivalence of operating with periodical flow reversal and integrated countercurrent heat exchange
A) Matros reactor; B) Temperature profiles in the Matros reactor with rapid flow reversal; C) Countercurrent reactor with catalyst at the wall; D) Schematic concentration and temperature profiles in natros and countercurrent reactors [11]

The mean gas temperature and mean catalyst temperature in the packing are considered separately. With a very frequent reversal of the flow direction, the catalyst temperature remains practically constant because the heat capacity of the packing is ca. 1000 times that of the gas, whereas the gas temperature is quasi-stationary compared to the packing temperature and therefore, depending on the flow direction, is somewhat below or above the packing temperature. To illustrate this, the principal temperature profiles are shown disproportionately far apart in Figure 30 B. These profiles are completely equivalent to those of a countercurrent heat exchange reactor in which the heat-exchanging partition is coated with catalyst (Fig. 30 C).

Since the stationary behavior of the countercurrent reactor can be calculated much more simply than the steady state of the reactor with periodic flow reversal, the equivalence model is suitable for rapid parameter studies. In addition, it permits straightforward assessment and interpretation of the somewhat unusual operating behavior of autothermal reactors. Considering the concentration profile corresponding to the temperature behavior in Fig. 30 D it can be seen that the reaction starts at an "ignition temperature" T_i and goes to rapid completion over a short section.

Thus it can be assumed to a first approximation that the temperature difference ΔT in Figure 30 D can be calculated from:

$$\Delta T = T_i + \Delta T_{ad} - T_0 \tag{5.1}$$

A detailed analysis shows that for more accurate estimates, heat exchange in the region of the reaction zone must also be included. In the following discussion the ignition temperature is therefore designated somewhat pragmatically as the temperature that lies ΔT_{ad} below the maximum temperature.

The gradient of the temperature curves below the ignition temperature can be derived from the conditions of countercurrent heat exchange with axial thermal conduction [11]:

$$\frac{dT}{dz} = \frac{U_w \cdot a_p \cdot \varepsilon \cdot \varrho_G \cdot c_{pG} \cdot v}{2 \cdot U_w \cdot a_p \cdot \lambda_{eff} + 4\left(\varepsilon \cdot \varrho_G \cdot c_{pG} \cdot v\right)} \cdot \Delta T_{ad} \tag{5.2}$$

This allows a simple graphical interpretation of the influence of the operating parameters on the reactor behavior.

Figure 31 A shows the change in the temperature and concentration profiles in the case of sufficiently quick reversal or countercurrent operation for gases with different ignition temperatures. The feed concentrations in each case are

chosen such that the same adiabatic temperature increase occurs. The plateau region of the maximum temperature becomes increasingly narrow with rising ignition temperature. If the ignition temperature lies above the point of intersection T_s of the two lateral straight lines, then operation in the ignited state is not possible. Accordingly, the narrower the plateau region of the maximum temperature, the closer the operating point is to the stability boundary; the wider the maximum temperature plateau, the more stable is the operation.

Figure 31. The influence of operating parameters on reactor behavior
A) Temperature and concentration profiles for gases with different ignition temperatures T_{I1}, T_{I2}; B) Influence of the feed concentration c_1^0, c_2^0, in the form of an adiabatic temperature rise ΔT_{ad} [11]

In this connection, the influence of catalyst deactivation can also be illustrated. Deactivation means a rise in the ignition temperature. In this case autothermal operation exhibits a fortunate tendency to self-stabilization: the maximum temperature adapts quasi-automatically to the rising ignition temperature, so that total conversion is ensured over a large activity range. If the catalyst activity is too low, then extinction from a state with highest maximum temperature occurs rather abruptly. In the case where the catalyst is deactivated by excess temperature, the self-stabilization of course leads to a vicious circle: the higher the maximum temperature, the greater the deactivation, and the higher the maximum temperature, etc.

The influence of inert front and end zones, which are frequently used with this type of reactor, can also easily be explained by means of Figure 31 A. If the ignition temperature is T_{I1} and the fixed bed of the reactor is inert up to the point z_2, then the catalytic reaction can be initiated at the earliest at z_2; the maximum temperature is thus raised from T_{I1} to T_{I2}, compared to the case of a continuously active catalyst.

Figure 31 B shows the influence of the feed concentration in the form of the adiabatic temperature rise on the temperature profile in the steady state. According to Equation (5.2), an increase in ΔT_{ad} broadens the temperature profile and raises the maximum temperature, whereby the increase in the maximum temperature above the ignition temperature is roughly proportional to ΔT_{ad}.

The above discussion refers to countercurrent operation and to the limiting case of a very rapid reversal of the flow direction. Normally during operation with periodic flow reversal, the reaction zone first migrates a certain extent into the reactor. As shown in Chapter 6, a relationship for the front migration velocity w can be derived from the total energy balance around the moving reaction front, and in the case of a large temperature rise ΔT and a small adiabatic temperature increase ΔT_{ad}, w can be approximated as follows:

$$w = \frac{\varepsilon \cdot \varrho_G \cdot c_{pG}}{\varepsilon \cdot \varrho_G \cdot c_{pG} + (1-\varepsilon) \cdot \varrho_s \cdot c_s} \cdot v_G \tag{5.3}$$

w from the above equation also corresponds to the migration velocity of a temperature front in a packing without reaction traversed with a velocity v_G. The influence of the period duration on the reactor behavior with periodic alternation of the flow direction can easily be estimated by

using Equation (5.3). For stable, ignited operation the maximum temperature and full conversion must be reached during the entire period. A semiperiod may only be so long that the temperature profile after reversal changes to the gradient specified in Equation (5.2), without the maximum temperature falling below the ignition temperature. Thus, a conservative estimate of the maximum semiperiod duration $\tau_{\max}$ is

$$\tau_{\max} = \frac{\Delta l_{\max}}{w}$$

with

$$\Delta l_{\max} = L - 2\,(T_{\mathrm{i}} - T_0) \cdot \frac{\mathrm{d}T}{\mathrm{d}z} \tag{5.4}$$

with catalyst bed length L as well as w, ΔT, and $\mathrm{d}T/\mathrm{d}z$ from Equations (5.3), (5.1), and (5.2), respectively. The behavior of autothermal combustion reactors with periodically alternating flow direction or integrated countercurrent heat exchange can be estimated by using the above equations [11].

6. Stability, Dynamics, and Control of Industrial Fixed-Bed Reactors

6.1. Introduction

Stability, dynamics, and control of fixed-bed reactors with strongly exothermic reactions has been studied in great detail since the early 1970s. The numerous publications could give the impression that this is a particularly critical reactor type with a large potential risk. In fact, the opposite is true. Compared to a liquid-phase reactor of the same size, a fixed-bed reactor with a gas-phase reaction contains a mass of reactants several orders of magnitude smaller. There is therefore no danger of a runaway exothermic reaction due to reactants accumulating in the reactor, especially as the heat capacity of the catalyst mass additionally damps the uncontrolled temperature rise.

Nevertheless, instabilities can arise in fixed-bed reactors, particularly with strongly exothermic reactions, and can lead to excess temperatures that can damage the catalyst and the reactor construction materials. Some causes of this are discussed below.

Fixed-bed reactors for industrial syntheses are generally operated over a long production period with almost constant operating parameters. The task of process control engineering is simply to keep these parameters optimal. In contrast, for supply or disposal plants that have several users or suppliers in a production network, there are frequent changes of feed material and throughput which require fast, automatic reaction control. Examples are fixed-bed reactors for synthesis gas production or off-gas treatment.

6.2. Parametric Sensitivity

Parametric sensitivity is the property typical of all highly exothermic reactions with high activation energy: small changes in the operating parameters can lead to large changes in the maximum temperature and yield. The reason is the exponential dependence of the reaction rate on temperature (Arrhenius law). Figure 32 shows calculated temperature profiles for partial oxidation in a wall-cooled, fixed-bed reactor tube of typical dimensions. In Figure 32 A only the main reaction is considered, while in Figure 32 B the total combustion to CO_2 and water is additionally taken into account. Since considerably more heat is liberated in the total combustion than in the desired main reaction, the sensitivity is increased considerably. As a measure of the parametric sensitivity, Figure 32 C shows the change in the maximum temperature via the cooling temperature for case B. The sensitivity is only moderate at low cooling temperatures, whereas above $T_c = 343\,°C$ small changes in T_c – and also in other parameters such as throughput, feed concentration, or pressure – lead to large changes in reactor behavior. Due to the unavoidable differences between individual tubes, multitubular reactors cannot be operated in the range of high parametric sensitivity. In this case the cooling temperature must be lowered to ca. 340 °C, and the tubes made longer to give a good conversion. This example emphasizes the requirement, discussed in Chapter 4, for making the conditions in the tubes of the tube bundle and in the cooling circuit as uniform as possible to avoid premature runaway reaction in individual tubes.

In the literature there are numerous runaway criteria with which operating ranges of high parametric sensitivity can be precalculated for

Figure 32. Parametric sensitivity of a partial oxidation reaction in a fixed-bed reactor of typical dimensions as a function of the coolant temperature T_C with $T(z=0)=T_C$
A) Temperature profile over reaction length (main reaction only); B) Temperature profile including total oxidation as side reaction; C) Maximum temperature T_{max} and yield as a function of coolant temperature T_C in case B; D) T_{max} as a function of T_C for both cases

known reaction kinetics [35–37]. In practice, however, these parameters are of only limited importance because they rarely take into account the peculiarities of individual cases. Sensitive reactions such as partial oxidation and partial hydrogenation are therefore generally tested in single-tube reactors of the same dimensions as those in the subsequent multitubular reactor. This allows the range of parametric sensitivity to be determined directly. Recalculation of the results for other tube diameters is only possible to a limited extent due to the uncertainties in the quantification of the heat-transfer parameters (see Section 2.3).

An operating fixed-bed reactor can enter the region of high parametric sensitivity through changes in the catalyst properties or operating conditions. Initially a few particularly sensitive tubes of the bundle will runaway, i.e., the reaction changes, for example, from a selective partial oxidation to a total combustion, and the temperature rises rapidly. In a multitubular reactor with thousands of tubes every tube cannot be equipped with temperature-profile measure-

ments; it is therefore likely that this runaway will remain undetected, especially if it involves only a few tubes. Although temperatures $> 1000\,°C$ can often be reached in the catalyst during such runaways, they are generally safe provided the tube is surrounded by heat-transfer medium. Because of the good heat transfer to the fluid the tube temperature remains close to that of the heat-transfer medium, and melting of the tube does not occur. The most certain method of detecting a runaway is on-line analysis of a product formed in the runaway reaction. For example, CO_2 can be monitored in the off-gas during the runaway-sensitive synthesis of ethylene oxide. If its concentration increases above a specified limit, the reactor must be shut down and for a certain period cooled to a lower cooling temperature before operation is recommenced. The reason why lowering the cooling temperature during operation does not extinguish the runaway reaction is discussed below.

6.3. Multiple Stationary States

The term parametric sensitivity applies when, according to Figure 32 D, a state quantity (T_{max}) is a single-valued function of a control quantity (T_C). However, in the runaway examples discussed in Section 6.1 this dependence can also be multiple valued. Then the runaway occurs not in a finite range of the control quantity, but on exceeding a fixed limit T_{ci}, often referred to as the ignition limit (Fig. 33). Between ignition and extinction of the runaway reaction (at $T_C = T_{cE}$), there is a hysteris region in which two stable stationary states are possible; at least one unstable intermediate state must lie between them. Various causes of multiple stationary states in fixed-bed reactors are known [38], [39]. Here, only the so-called thermal instabilities are discussed. They occur in exothermic reactions and arise because the evolution of heat increases exponentially with increasing temperature, while the heat removal at constant cooling temperature in-creases only linearly. Thus on exceeding a certain temperature limit, the heat release increases more rapidly than the heat removal, and the reaction ignites. On dropping below a second, lower temperature limit, the heat release becomes less than the heat removal, and the reaction is extinguished. In fixed-bed reactors, this process of ignition and extinction is associated with a local displacement of the main reaction zone. This can be most readily demonstrated by the example of an exothermic reaction in an adiabatic fixed-bed reactor.

Figure 33. Ignition – extinction hysteresis in the region of multiple steady states
Ignition occurs at $T_c = T_{cI}$ and extinction at $T_c = T_{cE}$.

Figure 34 shows the temperature profile for the catalytic total oxidation of ethane as a function of feed temperature. If this temperature is raised only slightly above the value for profile I, the reaction ignites in the rear portion of the reactor. Due to the axial thermal conduction in the developing steep temperature front, the main reaction zone moves slowly towards the entrance and is stabilized in position II a. The feed temperature must be lowered considerably to the value of position II b before the reaction extinguishes completely to profile III upon a further slight lowering of the feed temperature. A similar ignition – extinction behavior can also arise on changing the throughput or the feed concentration. The multiple stationary states I–II a and II b – III are partly a result of the axial backward conduction of heat in the reaction front. This represents a positive feedback which stabilizes either the ignited or the extinguished state. Mechanisms that transport heat from the end of the bed to its beginning stabilize multiple stationary states in a similar manner. These include the axial thermal conduction in the tube wall [41] and especially the influence of countercurrent cooling when the temperature of the coolant rises sig-

nificantly [42]. In autothermal reaction control (see Chap. 5), countercurrent cooling is used to stabilize the ignited state, which is desired in this case. However, in the case of strongly exothermic reactions with a risk of runaway, countercurrent cooling should generally not be used. The destabilizing effect of countercurrent cooling is demonstrated by the examples discussed in Figure 23. Another effect that can result in multiple stationary states is single-grain instability (see → Principles of Chemical Engineering, Chap. 7.2., → Principles of Chemical Engineering, Chap. 7.3.), which in fixed-bed reactors is always coupled with the effect of the reverse axial backward thermal conduction of heat [43] and intensifies the above-mentioned hysteresis behavior.

Figure 34. Measured axial temperature profile in the region of multiple steady states in an adiabatic fixed-bed reactor for the oxidation of ethane [40]
Ignition from profile I to II a; extinction from II b to III.

Whether a fixed-bed reactor goes runaway due to high parametric sensitivity or whether the reaction ignites on passing from a lower to a higher stationary state, the results in practice are the same: the maximum temperature increases rapidly to an unacceptably high value. However, in the case of parametric sensitivity, decreasing the cooling temperature or feed concentration during operation results in the maximum temperature returning to the safe range, whereas when multiple stationary states are present, this need not be the case. If a certain limit is exceeded on ignition, then the runaway reaction proceeds towards the ignited stationary state,

Figure 35. Measured (points) and calculated temperature profiles showing the transient of an adiabatic fixed-bed reactor for the methanation of CO and CO_2 [44]
A) Transition after increase in feed concentration; B) Transition after decrease in feed concentration; C) Transition after decrease in feed temperature
$SV = \dot{V}/V_R$ (space velocity)

even if the feed concentration or cooling temperature is lowered considerably. Extinction of the reaction occurs only on passing below the extinction limits, which particularly for strongly exothermic reactions lie far below the ignition conditions. In this case, the best strategy is to switch off the feed followed by inert gas purging, until all temperatures have fallen to uncritical values.

6.4. Migrating Reaction Zones

The discussion in the previous sections refers exclusively to the stationary state, i.e., the temperature and concentration profiles established after a sufficiently long operating time. However, in practice it is often more important in which way and with which velocity these profiles approach the next stationary state. This dynamic behavior of fixed-bed reactors with exothermic reactions exhibits several special features which are connected with the axial displacement of the main reaction zone in the form of a so-called migrating or moving reaction zone. The behavior can be most easily discussed by using the example of an adiabatic fixed-bed reactor.

Figure 35 shows measured temperature profiles for the methanation of traces of CO and CO_2. This reaction is carried out in an adiabatic fixed-bed reactor during ammonia synthesis gas production. If the feed concentration is increased, a new main reaction zone forms in the front part of the reactor, and the temperature rises here to a new maximum value. At the same time, the reactor outlet temperature initially drops below the original value before increasing to the new final value. This temporary reaction in the wrong direction is known as wrong-way behavior. More surprising is the wrong-way behavior in the examples of Figure 35 B (decrease in feed concentration) and Figure 35 C (decrease in feed temperature). Particularly in the latter case, the maximum temperature in the fixed bed initially increases rapidly while the main reaction zone moves slowly backwards out of the reactor. An explanation for this behavior in terms of the heat balance around a migrating combustion zone was first derived by Wicke and Vortmeyer [45]. In a migrating reaction zone that moves through an adiabatic fixed-bed reactor with velocity w due to lowering of the feed temperature to T^0 (Fig. 36), gas flows from the left into the reaction zone with velocity $v - w$ and temperature T^0 (v = gas velocity), while from the right catalyst enters the reaction zone with velocity w and temperature $T^0 + \Delta T$ and reacted gas leaves with velocity $v - w$ and the same temperature. The energy balance for the migrating reaction zone is thus:

$$\underbrace{\varepsilon \cdot A \cdot (v - w) \cdot \varrho_G \cdot c_{pG} \cdot \Delta T_{ad}}_{\text{Heat of reaction introduced and released with the gas}} = \underbrace{\varepsilon \cdot A \cdot (v - w) \cdot \varrho_G \cdot c_{pG} \cdot \Delta T}_{\text{Latent heat taken up by the gas}} + \underbrace{(1 - \varepsilon) \cdot A \cdot w \cdot \varrho_s \cdot c_s \cdot \Delta T}_{\text{Latent heat released by the packing}} \quad (6.1)$$

Figure 36. Derivation of the energy balance in a quasi-stationary migrating reaction zone in a fixed-bed reactor

It follows that for the temperature increase ΔT at the reaction front:

$$\Delta T = \frac{\Delta T_{ad}}{1 - \frac{(1-\varepsilon) \cdot w \cdot \varrho_s \cdot c_s}{\varepsilon \cdot (v - w) \cdot \varrho_G \cdot c_{pG}}} \quad (6.2)$$

Thus for $w > 0$ (i.e., reaction zone moving downstream), the temperature increase of the reaction front is always larger than the adiabatic temperature rise because the entering gas is heated by the hot catalyst (which is cooled) and because of the liberated heat of reaction.

The examples of autothermal reaction control with periodic reversal of the flow direction (Section 5.2) show that the temperature increase of the combustion zone can be conserably higher than the adiabatic temperature rise. According to Equation (6.2), the temperature increase in the combustion can even rise to arbitrarily high values when the denominator approaches zero; i.e.,

the migration velocity reaches the critical limit W_{crit}:

$$W_{\mathrm{crit}} = \frac{\varepsilon \cdot \varrho_{\mathrm{G}} \cdot c_{\mathrm{pG}}}{\varepsilon \cdot \varrho_{\mathrm{G}} \cdot c_{\mathrm{pG}} + (1-\varepsilon) \cdot \varrho_{\mathrm{s}} \cdot c_{\mathrm{s}}} \cdot v \tag{6.3}$$

In this case, the reaction front moves with exactly the velocity of a temperature front without reaction. If dispersion effects such as thermal conduction are neglected, the liberated heat of reaction can no longer be transported out of the reaction zone and thus accumulates there.

The migration velocity w of a reaction front can generally not be preset from outside, but is instead a result of the complex interaction of material and heat transport with the reaction, as is approximately described by fixed-bed reactor models. However, there is one noteworthy exception, which occurs when the catalyst in the main reaction zone is deactivated with exactly the critical velocity.

In the example of Figure 37, this deactivation was carried out deliberately by adding a catalyst poison (thiophene) to the feed at time $t = 0$. This results in a deactivation of the nickel catalyst by irreversible adsorption of thiophene, whereby the adsorption front moves through the bed with velocity w, pushing the reaction front before it. The accidental addition of a catalyst poison can thus lead to migrating combustion zones with very high maximum temperatures in both adiabatic and nonadiabatic reactors, if a migration velocity in the critical range is initiated.

Figure 37. Migrating reaction front in an adiabatic fixed-bed reactor due to intentional catalyst poisoning (hydrogenation of benzene over nickel) [46]
At $t = 0$, a catalyst poison thiophene is added to the feed.

Particularly problematic is catalyst deactivation due to excess temperature deactivation of the catalyst because it results in a vicious circle: the catalyst is deactivated in the region of the main reaction zone due to an excessive maximum temperature. This leads to a migrating combustion zone in which the maximum temperature rises further, and so on. Impressive examples of this behavior in wall-cooled reactor tubes have been described by Blaum [47] and Emig [48].

Figure 38 shows measured profiles in a bed of thermally unstable nickel catalyst in the case of CO oxidation. Figure 39 shows the temperature profile for vinyl acetate synthesis over zinc acetate. Since the zinc acetate catalyst decomposes above 500 K, the result is a reaction front that moves downstream. The dip in the temperature profile (d) clearly indicates deactivation at the position of the original temperature maximum. In the past, this was sometimes cited as a good example of parametric sensitivity. The above discussion, however, shows that the cause of the "runaway" reaction should rather be attributed to the dynamic influence of the migrating combustion zone.

Figure 38. Migrating combustion zone in the case of CO oxidation over nickel, caused by thermal deactivation of the catalyst [47]

Figure 39. Migrating reaction front during the synthesis of vinyl acetate over zinc acetate, caused by thermal damage to the catalyst [48]
a) 60 min; b) 75 min; c) 100 min; d) 165 min

6.5. Safety Aspects

Because of the small mass storage capacity compared to liquid-phase reactors, the danger of sudden reaction of accumulated reactants in gas-phase fixed-bed reactors is low. Leaving out the peculiarities of individual cases, the following safety risks can be assumed for fixed-bed reactors:

1) Leaks which result in the release of large amounts of gas or vapor and the formation of explosive clouds
2) Leaks resulting in release of large amounts of liquid heat-transfer media (oils, salt melts)
3) Occurrence of ignitable or decomposable gas mixtures in the reactor
4) Melting of the reactor due to a runaway reaction

The safety aspects of liquid heat-transfer media are discussed in Section 4.3.1. Ignitable gas mixtures can arise particularly during partial oxidation reactions. They are especially critical where large packing-free volumes are present. This is the case in the inflow and outflow hoods of the reactor, while in the reactor tubes the catalyst packing dampens the propagation of a flame front due to its heat capacity. Complete avoidance of ignitable mixture is generally not possible in partial oxidations because at least during mixing of the gas streams prior to the reactor the ignition limit is exceeded locally. Nevertheless, in the past, operation of fixed-bed reactors with ignitable mixtures was avoided, either by dilution with inert gas or by operating in the nonstoichiometric range. The former requires additional efforts for heating, cooling, and separation of the inert gas, while the latter gives only low conversions of the reactants in a single pass. New developments in partial oxidation therefore aim for stoichiometric operation in the ignitable range [51]. A prerequisite for this is pressure-resistant construction with check valves and flame barriers so a possible that ignition is confined to the interior of the reactor.

Figure 40. Effect of disturbances in the coolant circuit of a multitubular reactor (Fig. 41) with a partial oxidation reaction [49]
A) Profile of maximum temperature with time after change of the valve position ($\Delta\dot{m}_c$), after pump failure ($v_c \to 0$), and after valve closure ($\dot{m}_c \to 0$); B) Temperature profile after failure of the coolant circulation pump

Melting of reactor tubes during runaway reaction is only to be feared in multitubular reactors

if the respective tube is not surrounded by heat-transfer medium. Thus, appropriate design must ensure that running dry of reactor tubes cannot occur. In the case of corrosive reaction gases, apparatus for the detection of leaks caused by corrosion must be provided, particularly when pressurized or boiling water is used as coolant.

If the coolant circulation is interrupted during an exothermic reaction, the reactor must be shut down. Nevertheless, the heat storage capacity of the catalyst and the heat-transfer medium surrounding the tubes allows sufficient reaction time for controlled shutdown of the reactor. This is shown by simulation calculations for a multitubular reactor (Fig. 40) with a partial oxidation reaction. It was assumed that at $t = 0$ either the circulating pump fails or that the regulating valve in the pipe to the steam generator closes. As can be seen in Figure 40, there is a time span of 200 or 350 s, respectively before the maximum temperature in the catalyst reaches unpermissably high values.

In large-volume adiabatic fixed-bed reactors, local temperature maxima (hot spots) can form due to nonuniform distribution of the flow or inhomogeneities in the catalyst packing. They can be intensified by front migration phenomena (Section 6.4) and can lead to thermal damage of the reactor. This is particularly true of runaway-prone reactions such as partial hydrogenation with a large excess of hydrogen, which can change from selective hydrogenation to complete methanation. This can be detected by online analysis of methane in the product.

6.6. Control of Fixed-Bed Reactors

The control of fixed-bed reactors for chemical synthesis generally only involves maintaining the operating conditions at the optimum values. For runaway-prone reactions, this is supplemented by an extensive measurement and control system with built-in redundancy for giving alarm and shutting down the reactor. Slow changes in catalyst activity during multistage adiabatic reactors are corrected by "manual" adjustment of the set value for the feed temperature of each stage in multitubular reactors or by the adjustment of the heat-transfer medium temperature. The target is usually to keep the desired conversion constant. Mass flow control, feed stoichiometry control, control of the total pressure (generally in the reactor outlet), as well as feed temperature and heat-transfer medium temperature control are therefore the most important automatic control circuits in fixed-bed reactors.

In the following, some special points concerning the cooling temperature control of multitubular fixed-bed reactors are considered. In a multitubular reactor with molten-salt cooling (Fig. 41) the cooling temperature is controlled by a control unit in the connecting channel to the steam generator. In this way, varying amounts of colder salt melt can be introduced into the circulation system, with effective mixing taking place in the circulating pump. This cooling circuit can be unstable [37]. Since the reaction rate or liberated heat $\dot{Q}_{\mathrm{E}}$ increases exponentially with increasing cooling temperature, while the heat removed in the steam generator $\dot{Q}_{\mathrm{A}}$ increases only linearly, the conditions shown in Figure 42 may occur in the desired state. On a slight increase of the cooling temperature above $T_{\mathrm{C,\,set}}$, the cooling circuit warms up since $\dot{Q}_{\mathrm{E}} > \dot{Q}_{\mathrm{A}}$, and on dropping slightly below $T_{\mathrm{C,\,set}}$ cools down because $\dot{Q}_{\mathrm{A}} > \dot{Q}_{\mathrm{E}}$. Because of the large thermal inertia, however, the unstable operating point can easily be stabilized via the control TC (Fig. 41).

Figure 41. Temperature control in a fixed-bed reactor with molten-salt cooling

Figure 42. Heat generation $\dot{Q}_E$ and heat removal $\dot{Q}_A$ for the cooled multitubular reactor of Figure 41 as a function of coolant temperature [37]

To obtain optimum conversion, attempts are usually made to operate with a cooling temperature so high that a previously determined maximum temperature in the reactor is just reached but not exceeded. The maximum temperature can be measured by equipping several tubes of the bundle with multiple thermoelements which allow simultaneous measurement of, for example, 10 – 20 temperatures along the tube length. This allows regulation of the maximum temperature, which influences the set point of the cooling temperature in a cascade circuit. However, determining the maximum temperature from various discrete measurement points is not trivial [50]. Therefore, methods for the model-based measurement techniques should be used here.

In the case of cooling with a boiling medium, a multitubular reactor generally has the structure shown in Figure 43. The cooling temperature here corresponds to the boiling temperature in the vapor drum, which is controlled by a control unit in the saturated vapor line. The cooling temperature control is thus performed by controlling the saturated vapor pressure in the vapor drum. The dynamics of the natural convection cooling circuit has a particular effect on the behavior of this control loop. Thus rapid lowering of the cooling temperature via the drum pressure by opening the saturated vapor valve leads to increased boiling of the coolant in the circuit. If the liquid boils into the downpipe, the natural circulation is temporarily interrupted. Furthermore, the increase in volume associated with boiling pushes liquid into the vapor drum, which can result in liquid entering the vapor line. This is discussed in detail in [49].

Figure 43. Multitubular reactor with evaporative cooling

If the fixed bed to be regulated is part of a supply or off-gas treatment plant that is subject to large variations in feed concentration and throughput, then a fixed control is difficult, mainly because of the complex wrong-way behavior (see Section 6.4). Hence, in practice a catalyst with a wide operating range is used and the reactor is made larger.

The article gives an overview on fundamentals and applications of fluidized-bed technology. Some basic fluid-mechanical principles—minimum fluidization velocity, status diagram, gas distribution, bubble development, and solids entrainment and elutriation—are presented at the beginning, followed by a detailed discussion of circulating fluidized beds, downers, and attrition effects in fluidized-bed systems. Sections on solids mixing, gas mixing, and heat and mass transfer in fluidized beds complete the fundamentals section, which is followed by an overview on industrial applications. Fluidized-bed processes for heterogeneous catalytic gas-phase reactions, for the polymerization of olefins, for homogenous gas-phase reactions, gas–solid reactions and applications in biotechnology are described in detail. A final chapter is devoted to the modeling of fluidized-bed reactors.

λ	average life time of a bubble, s
μ	solid-to-gas mass flow ratio
ν	kinematic viscosity, m^2/s
ν_{ij}	stoichiometric number of species i in reaction j
ϱ_f	fluid density, kg/m^3
ϱ_s	solids density, kg/m^3
ϑ	stress history parameter, defined by Equation (54)
ϑ_b	parameter, defined by Equation (23)
ψ	pressure ratio, defined by Equation (28)

1. Introduction

1.1. The Fluidization Principle

In fluidization an initially stationary bed of solid particles is brought to a "fluidized" state by an upward stream of gas or liquid as soon as the volume flow rate of the fluid exceeds a certain limiting value $\dot{V}_{\mathrm{mf}}$ (where mf denotes minimum fluidization). In the fluidized bed, the particles are held suspended by the fluid stream; the pressure drop Δp_{fb} of the fluid on passing through the fluidized bed is equal to the weight of the solids minus the buoyancy, divided by the cross-sectional area A_{t} of the fluidized-bed vessel (Fig. 1):

$$\Delta p_{\mathrm{fb}} = \frac{A_{\mathrm{t}} \cdot H \cdot (1-\varepsilon) \cdot (\varrho_{\mathrm{s}} - \varrho_{\mathrm{f}}) \cdot g}{A_{\mathrm{t}}} \tag{1}$$

In Equation (1), the porosity ε of the fluidized bed is the void volume of the fluidized bed (volume in interstices between grains, not including any pore volume in the interior of the particles) divided by the total bed volume; ϱ_{s} is the solids apparent density; and H is the height of the fluidized bed.

In many respects, the fluidized bed behaves like a liquid. The bed can be stirred like a liquid; objects of greater specific gravity sink, whereas those of lower specific gravity float; if the vessel is tilted, the bed surface resumes a horizontal position; if two adjacent fluidized beds with different bed heights are connected to each other, the heights become equal; and the fluidized bed flows out like a liquid through a lateral opening. Particularly advantageous features of the fluidized bed for use as a reactor are excellent gas–solid contact in the bed, good gas–particle heat and mass transfer, and high bed–wall and bed–internals heat-transfer coefficients.

The fluidization principle was first used on an industrial scale in 1922 for the gasification of fine-grained coal [1]. Since then, fluidized beds have been applied in many industrially important processes. The present spectrum of applications extends from a number of physical processes, such as cooling–heating, drying, sublimation–desublimation, adsorption–desorption, coating, and granulation, to many heterogeneous catalytic gas-phase reactions as well as noncatalytic reactions.

What follows is a survey of the fluid mechanical principles of fluidization technology, gas and solid mixing, gas–solid contact in the fluidized bed, typical industrial applications, and approaches to modeling fluidized-bed reactors. Further information is given in textbooks (e.g., [2]) and monographs (e.g., [3 – 8]). Summary treatments can also be found in [9 – 19]. Other useful literature includes reports of the Engineering Foundation Conferences on Fluidization [20 – 22], the Circulating Fluidized Bed Conferences (e.g., [23 – 25], and—for use of the fluidized bed in energy technology—the Fluidized Bed Combustion Conferences (e.g., [26 – 28]).

1.2. Forms of Fluidized Beds

As the volume flow rate $\dot{V}$ or the superficial velocity $u = \dot{V}/A_{\mathrm{t}}$ of the fluid increases beyond

Figure 1. Pressure drop in flow through packed and fluidized beds

Figure 2. Forms of gas–solids fluidized beds

the value $\dot{V}_{\mathrm{mf}}$ or u_{mf} (Fig. 2 A) corresponding to the minimum fluidization point, one of two things happens: in *fluidization with a liquid*, the bed begins to expand uniformly; in *fluidization with a gas*—a process of greater industrial importance and the one discussed almost exclusively in the following material—virtually solids-free gas bubbles begin to form (Fig. 2 B). The local mean bubble size increases rapidly with increasing height above the grid because of coalescence of the bubbles. If the bed vessel is sufficiently narrow and high, the bubbles ultimately fill the entire cross section and pass through the bed as a series of gas slugs (Fig. 2 C). As the gas velocity increases further, more and more solids are carried out of the bed, the original, sharply defined surface of the bed disappears, and the solids concentration comes to decrease continuously with increasing height. To achieve steady-state operation of such a "turbulent" fluidized bed (Fig. 2 D), solids entrained in the fluidizing gas must be collected and returned to the bed. The simplest way to do this is with a cyclone integrated into the bed vessel and a standpipe dipping into the bed. A further increase in gas velocity finally leads to the circulating fluidized bed (Fig. 2 E), which is characterized by a much lower average solids concentration than the previous systems. The high solids entrainment requires an efficient external solids recycle system with a specially designed pressure seal (shown as a siphon in Fig. 2 E).

1.3. Advantages and Disadvantages of the Fluidized-Bed Reactor

The major advantages of the (gas–solid) fluidized bed as a reaction system include

1) Easy handling and transport of solids due to liquid-like behavior of the fluidized bed
2) Uniform temperature distribution due to intensive solids mixing (no hot spots even with strongly exothermic reactions)
3) Large solid–gas exchange area by virtue of small solids grain size
4) High heat-transfer coefficients between bed and immersed heating or cooling surfaces
5) Uniform (solid) product in batchwise process because of intensive solids mixing

Set against these advantages are the following disadvantages:

1) Expensive solids separation or gas purification equipment required because of solids entrainment by fluidizing gas
2) As a consequence of high solids mixing rate, nonuniform residence time of solids, backmixing of gas, and resulting lower conversion

3) In catalytic reactions, undesired bypass or broadening of residence-time distribution for reaction gas due to bubble development
4) Erosion of internals and attrition of solids (especially significant with catalysts), resulting from high solids velocities
5) Possibility of defluidization due to agglomeration of solids
6) Gas–solid countercurrent motion possible only in multistage equipment
7) Difficulty in scaling-up

Table 1 compares the fluidized-bed reactor with alternative gas–solid reaction systems: fixed-bed, moving-bed, and entrained-flow reactors.

2. Fluid-Mechanical Principles

2.1. Minimum Fluidization Velocity

The minimum fluidization point, which marks the boundary between the fixed- and the fluidized-bed conditions, can be determined by measuring the pressure drop Δp across the bed as a function of volume flow rate $\dot{V}$ (Fig. 1). Measurement should always be performed with decreasing gas velocity, by starting in the fluidized condition.

Only for very narrow particle-size distributions, however, does a sharply defined minimum fluidization point occur. The broad size distributions commonly encountered in practice exhibit

Table 1. Comparison of gas–solid reaction systems [2, 18]

Characteristics	Fixed bed	Moving bed	Fluidized bed	Entrained flow
Suitability for heterogeneous catalytic gas-phase reactions	only for catalyst that is deactivated very slowly	can also be used with catalyst that is rapidly deactivated		
	catalyst attrition negligible	catalyst attrition may be critical, depending on operating conditions		
	plug flow of gas ensures high gas conversion		backmixing of gas due to mixing motion of solids and bubble-gas bypass lead to lower conversion	gas in virtually plug flow; high conversion possible
Suitability for gas–solid reactions	unsuitable for continuous processes; batchwise operation yields nonuniform product	for uniform feed particle size with low fines content; large reactor capacities possible	no special requirements for feed particle-size distribution; high fines content also possible; continuous operation yields uniform product	possible for fast reactions; recycle of unreacted fines often difficult
Temperature distribution	danger of hot spots with exothermic reactions	temperature gradients can be held within limits by virtue of high solids circulation and high gas throughput	high solids mixing ensures uniform temperature distribution in bed; temperature control by heat exchangers immersed in bed or by admission and removal of solids	axial temperature gradients can be held within limits by high solids circulation
Heat supply and removal, heat exchange	poor heat exchange; heat transport limits scale-up	poor heat exchange; due to high heat capacity of solids transport of large quantities of heat by way of circulating solids	very efficient heat exchange, good heat transport by solids	properties intermediate between fluidized bed and moving bed
Particle size	large pellets (ca. 8–20 mm), as uniform as possible; no fines	medium size (ca. 2–6 mm) and uniform; no fines	broad particle-size distribution (ca. 0.02–6 mm); high fines content acceptable	fine (0.02–0.5 mm), with narrow particle-size distribution

a blurred range; conventionally, the minimum fluidization point is defined as the intersection of the extrapolated fixed-bed characteristic with the line of constant bed pressure drop typical of the fluidized bed (Fig. 1).

The measurement technique already contains the possibility of calculating the minimum fluidization velocity u_{mf}: The pressure drop in flow through the polydisperse fixed bed at the point $u = u_{\mathrm{mf}}$, given, for example, by the Ergun relation [29] (→ Fluid Mechanics), is set equal to the fluidized-bed pressure drop given by Equation (1). From the Ergun relation

$$\frac{\Delta p}{h} = 4.17 \cdot S_v^2 \cdot \frac{(1-\varepsilon)^2}{\varepsilon^3}\,\eta u + 0.29 S_v \cdot \frac{1-\varepsilon}{\varepsilon^3}\,\varrho_{\mathrm{f}}\,u^2$$

it follows

$$u_{\mathrm{mf}} = 7.14\,(1-\varepsilon_{\mathrm{mf}})\,\nu \cdot S_v \cdot \left[\sqrt{1+0.067\,\frac{\varepsilon_{\mathrm{mf}}^3}{(1-\varepsilon_{\mathrm{mf}})^2} \cdot \frac{(\varrho_{\mathrm{s}}-\varrho_{\mathrm{f}})\cdot g}{\varrho_{\mathrm{f}}\,\nu^2} \cdot \frac{1}{S_v^3}} - 1\right] \tag{2}$$

Accordingly, to calculate u_{mf}, the characteristics of the gas (ϱ_{f}, ν), the density ϱ_{s} of the particles, the porosity $\varepsilon_{\mathrm{mf}}$ of the bed at minimum fluidization, and the volume-specific surface area S_v of the solids must be known. The specific surface area defined by

$$S_v = \frac{\text{surface area of all particles in the bed}}{\text{volume of all particles in the bed}}$$

(this takes into account only the external area, which governs hydraulic resistance, not the pore surface area as in porous catalysts) cannot be determined very exactly in practice. Hence u_{mf} should not be calculated on the basis of the measured particle-size distribution of a representative sample of the bed solids; instead, it is better measured directly. Equation (2) can be employed advantageously to calculate u_{mf} in an industrial-scale process on the basis of minimum fluidization velocities measured in the laboratory under ambient conditions [30].

An equation from Wen and Yu [31] can be used for approximate calculations:

$$Re_{\mathrm{mf}} = 33.7\left(\sqrt{1+3.6\times10^{-5}\cdot Ar} - 1\right) \tag{3}$$

where

$$Re_{\mathrm{mf}} = \frac{u_{\mathrm{mf}} d_{\mathrm{p}}}{\nu} \tag{4}$$

$$Ar = \frac{g d_{\mathrm{p}}^3}{\nu^2} \cdot \frac{\varrho_{\mathrm{s}}-\varrho_{\mathrm{f}}}{\varrho_{\mathrm{f}}} \tag{5}$$

Here the surface mean or Sauter diameter calculated from the mass–density distribution $q_3\,(d)$ of the particle diameters

$$d_{\mathrm{p}} = \frac{1}{\int\limits_{d_{\min}}^{d_{\max}} d^{-1} \cdot q_3\,(d)\,\mathrm{d}\,(d)} \tag{6}$$

should be used for the characteristic particle diameter d_{p}.

Both the Ergun approach and the Wen and Yu simplification have been confirmed experimentally over a wide range of parameters. More recently, Vogt et al. [32] found that Equations (2) and (3) are also applicable to high-pressure fluidized beds in which the fluid is under supercritical conditions

2.2. Expansion of Liquid–Solid Fluidized Beds

The uniform expansion of a bed on fluidization with a liquid can be described by

$$\frac{u}{u_{\mathrm{t}}} = \varepsilon^n \tag{7}$$

according to Richardson and Zaki [33]. Here u_{t} is the terminal velocity of isolated single particles; the exponent n is given as follows, provided the particle diameter is much smaller than that of the vessel:

$$n = \begin{cases} 4.65 & 0 < Re_{\mathrm{t}} \leq 0.2 \\ 4.4 \cdot Re_{\mathrm{t}}^{-0.03} & 0.2 < Re_{\mathrm{t}} \leq 1 \\ 4.4 \cdot Re_{\mathrm{t}}^{-0.1} & 1 < Re_{\mathrm{t}} \leq 500 \\ 2.4 & 500 < Re_{\mathrm{t}} \end{cases} \tag{8}$$

The Reynolds number used above is calculated via the single-particle terminal velocity u_{t}:

$$Re_{\mathrm{t}} = \frac{u_{\mathrm{t}} \cdot d_{\mathrm{p}}}{\nu} \tag{9}$$

2.3. Fluidization Properties of Typical Bed Solids

In fluidization with gases, solids display characteristic differences in behavior that can also affect the operating characteristics of fluidized-bed reactors. Geldart has proposed an empirically based classification of solids into four groups (A to D) by fluidization behavior [34].

The parameters employed are those crucial for fluidization properties: the mean particle diameter (d_p) and the density difference ($\varrho_s - \varrho_f$) between solid and fluid. Figure 3 shows the Geldart diagram with the interclass boundaries theoretically established by MOLERUS [35].

Figure 3. Geldart diagram (boundaries according to MOLERUS [35])
For explanation see text

Solids of group C are very fine-grained, cohesive powders (e.g., flour, fines from cyclones and electrostatic filters) that virtually cannot be fluidized without fluidization aids. The adhesion forces between particles are stronger than the forces that the fluid can exert on the particles. Gas flow through the bed forms channels extending from the grid to the top of the bed, and the pressure drop across the bed is lower than the value from Equation (1). Fluidization properties can be improved by the use of mechanical equipment (agitators, vibrators) or flowability additives, e.g., Aerosil.

Solids of group A have small particle diameters (ca. 0.1 mm) or low bulk densities; this class includes catalysts used e.g., in the fluidized-bed catalytic cracker. As the gas velocity u increases beyond the minimum fluidization point, the bed of such a solid first expands uniformly until bubble formation sets in at $u = u_{mb} > u_{mf}$. The bubbles grow by coalescence but break up again after passing a certain size. At a considerable height above the gas distributor grid, a dynamic equilibrium is formed between bubble growth and breakup. If the gas flow is cut off abruptly, the gas storage capacity of the fluidized suspension causes the bed to collapse rather slowly.

Group B solids have moderate particle sizes and densities. Typical representatives of this group are sands with mean particle diameters between ca. 0.06 and 0.5 mm. Bubble formation begins immediately above the minimum fluidization point. The bubbles grow by coalescence, and growth is not limited by bubble splitting. When the gas flow is cut off abruptly, the bed collapses quickly.

Group D includes solids with large particle diameters or high bulk densities; examples are sands with average particle diameters > 0.5 mm. Bubbles begin to form just above the minimum fluidization point, but the character of bubble flow is markedly different from that in group B solids: group D solids are characterized by the formation of "slow" bubbles (Section 2.7). On sudden stoppage of the gas flow, the bed also collapses suddenly.

2.4. State Diagram of Fluidized Bed

Whereas the onset of the fluidized state can be described by the minimum fluidization velocity, the bed operating range and the gas velocity needed to create a given fluidized state can be estimated with the help of the fluidized-bed state diagram (Fig. 4) devised by REH [36]. This plot shows the fluid mechanical resistance characteristics of the fixed bed, fluidized bed, and pneumatic transport. The ordinate is the quantity

$$\frac{3}{4}\frac{u^2}{g \cdot d_p} \cdot \frac{\varrho_f}{(\varrho_s - \varrho_f)}$$

and the abscissa is the Reynolds number Re_p formed with the fluidization velocity u and the particle diameter d_p. The state parameter in the fluidized-bed region is the mean bed porosity ε. The use of the diagram is facilitated by an auxiliary grid with lines of constant M and constant Archimedes number. While the dimensionless groups plotted as ordinate and abscissa each contain both the particle diameter and the fluidization velocity, this is not the case with the parameters Ar and M defined by

$$Ar = \frac{g \cdot d_p^3}{\nu^2} \cdot \frac{(\varrho_s - \varrho_f)}{\varrho_f} \tag{10}$$

$$M = \frac{u^3}{g \cdot \nu} \cdot \frac{\varrho_f}{(\varrho_s - \varrho_f)} \tag{11}$$

The Reh status diagram can answer a number of practical questions. If, for example, the properties of the gas (ρ_f, ν) and the solid (d_p, ρ_s) and the fluidization velocity u are given, the calculation of Ar and Re_p yields, via the status point S in the diagram (Fig. 4), the average voidage ε in the fluidized bed. Taking the line M = const. through S at the intersection with the line $\varepsilon \to 1$ at S_1 gives information on the particle size which is just elutriated when a particles with a size distribution are fluidized, and the intersection of the same line with the fixed-bed limit $\varepsilon = 0.4$ (S_2) indicates the particle size at which fluidization will break down if agglomeration occurs. The line Ar = const. through S can be used to find the minimum fluidization velocity at S_3 or—as a measure of the upper limit of fluidization—the maximum fluidizing velocity at S_4.

Figure 4. Reh status diagram with status points S and S_1–S_4 (for explanation, see text)

An important practical point is that the state diagram implies a classification scheme that relates various fluidized-bed systems to one another [37, 38] (Fig. 5). When a new fluidized-bed process is being designed, the position of the state point in the diagram will identify related fluidized-bed systems with potentially similar operating problems.

2.5. Gas Distribution

The gas distribution device must satisfy the following requirements:

1) Ensure uniform fluidization over the entire cross section of the bed (especially important for shallow beds)
2) Provide complete fluidization of the bed without dead spots where, for example, deposits can form
3) Maintain a constant pressure drop over long operation periods (outlet holes must not become clogged)

Often, the gas distributor design must also prevent solids from raining through the grid both during operation and after the bed has been shut off.

Porous plates of glass, ceramics, metal, or plastic are commonly used as gas distributors in *laboratory apparatus*; a variety of designs are used in *pilot-plant* and *full-scale fluidized-bed* reactors (see Fig. 6). Many more designs can be found, for example, in [2] and [39].

The principal requirement—uniform distribution of fluidizing gas over the bed cross section—can be met if the pressure drop Δp_d across the gas distribution grid is large enough. Suggested values for the ratio $\Delta p_d / \Delta p_{fb}$ are 0.1–0.3 (with a minimum Δp_d of 3.5 kPa) [40], 0.2–0.4 [41], and > 0.3 [42].

For a given pressure drop Δp_d the gas velocity in the nozzle u_o can be calculated from

$$\Delta p_d = \frac{\varrho_o}{2} \cdot C_D \cdot u_o^2$$

where ϱ_o is the gas density in the orifice and C_D is the drag coefficient. Applying the continuity equation

$$\dot{V} = N_o \cdot A_o \cdot u_o$$

either the number of nozzles N_o or the cross-sectional area of the individual nozzle A_o can be calculated for a given gas flow rate $\dot{V}$.

Problems related to the design of gas distributors are attrition of solids (see Section 2.11), erosion, and back-flow of solids. Erosion may occur at the distributor plate and at neighboring

Figure 5. Reh's fluidized-bed state diagram with operating regions of different reaction systems
a) Circulating fluidized bed; b) Fluidized-bed roaster; c) Bubbling fluidized bed; d) Shaft furnace; e) Moving bed

Figure 6. Industrial gas distributors
A) Perforated plate; B) Nozzle plate; C) Bubble-cap plate

nozzles or walls due to gas jets as well as at the nozzle itself. Back-flow of solids into the windbox is caused by pressure fluctuations. In order to prevent this either the design pressure drop has to be larger than the pressure fluctuations or—if this is not feasible for economic reasons—a design must be chosen which tolerates short periods of gas flow reversal without permitting the solids to penetrate into the windbox. For the latter case the bubble cap design has turned out to be advantageous [43].

In the operation of fluidized-bed reactors, the quadratic response ($\Delta p_{\mathrm{d}} \sim u^2$) of industrial gas-distributor designs must be kept in mind, because even if the fluidization velocity is lowered only slightly, an unacceptably low pressure drop across the gas distributor may occur. Industrial experience with different distributor designs, practical design rules, and a discussion of distributor-related problems, such as weepage into the windbox and erosion by grid jets and at grid nozzles, has been compiled in [44].

2.6. Gas Jets in Fluidized Beds

Gas jets can form at the outlet openings of industrial gas distributors and also where gaseous reactants are admitted directly into the fluidized bed. A knowledge of the geometry of such jets, in particular the depth of penetration, is important for the implementation of chemical operations in fluidized-bed reactors, and not just from the standpoint of reaction engineering. It is also vital for reasons of design: the strongly erosive action of these jets means that internals, such as heat-exchanger tubes, must not be located within their range.

The literature contains many empirical correlations for estimating the mean depth of jet penetration L (e.g., [2 – 4]); these must, however, be used with care and, whenever possible, only within the range of parameter values for which they were derived. By way of example, Merry gives the following correlations for *vertical gas* jets [45]:

$$\frac{L}{d_{\mathrm{o}}} = 5.2 \left(\frac{\varrho_{\mathrm{f}} d_{\mathrm{o}}}{\varrho_{\mathrm{s}} d_{\mathrm{p}}}\right)^{0.3} \left[1.3 \left(\frac{u_{\mathrm{o}}^2}{g d_{\mathrm{o}}}\right)^{0.2} - 1\right] \tag{12}$$

and for *horizontal jets* [46]:

$$\frac{L}{d_{\mathrm{o}}} = 5.25 \left[\frac{\varrho_{\mathrm{o}} u_{\mathrm{o}}^2}{(1-\varepsilon)\, \varrho_{\mathrm{s}} g\, d_{\mathrm{p}}}\right]^{0.4} \left(\frac{\varrho_{\mathrm{f}}}{\varrho_{\mathrm{s}}}\right)^{0.2} \cdot \left(\frac{d_{\mathrm{p}}}{d_{\mathrm{o}}}\right)^{0.2} - 4.5 \tag{13}$$

Here d_{o} is the diameter of the outlet opening, u_{o} is the outflow velocity, and ϱ_{o} is the density of the jet gas.

2.7. Bubble Development

For many applications, especially physical operations and noncatalytic reactions, the state of a fluidized bed can adequately be described in terms of a single quantity averaged over the entire bed, such as the mean bed porosity ε. In contrast, the design of fluidized-bed catalytic reactors requires that local fluid-flow conditions also be taken into account.

The local fluid mechanics of gas–solid fluidized beds are determined by the existence of bubbles, which influence the performance of fluidized-bed equipment in several ways: the stirring action and convective solids transport by the rising bubbles are helpful; the resulting intensive solids motion produces a uniform temperature throughout the fluidized bed and rapid heat transfer between the bed and the heating or cooling tubes submerged in it. The bubbles and the motion of solids that they cause, however, also have some drawbacks: attrition of solid particles, erosion of internals, and increased solids entrainment by bubbles bursting at the bed surface. The existence of bubbles is particularly detrimental in the case of a heterogeneous catalytic gas-phase reaction, because the bypass of reactant gas in the bubble phase limits the conversion achieved in the fluidized bed.

The ultimate cause of bubble formation is the universal tendency of gas–solid flows to segregate. Many studies on the theory of stability (e.g., [3, 4]) have shown that disturbances induced in an initially homogeneous gas–solid suspension do not decay but always lead to the formation of voids. The bubbles formed in this way exhibit a characteristic flow pattern whose basic properties can be calculated with the model of Davidson and Harrison [47]. Figure 7 shows the streamlines of the gas flow relative to a bubble rising in a fluidized bed at minimum fluidization conditions ($\varepsilon = \varepsilon_{\mathrm{mf}}$). The characteristic parameter is the ratio α of the bubble's upward

velocity u_b to the interstitial velocity of the gas in the suspension surrounding the bubble:

$$\alpha = \frac{u_b}{u_{mf}/\varepsilon_{mf}} \tag{14}$$

Figure 7. Gas flow for isolated rising bubbles in the Davidson model [47]

The case $\alpha > 1$ is typical for solids of Geldart groups A and B. The gas rising in the bubble flows downward again in a thin layer of suspension ("cloud") surrounding the bubble. An important point for heterogeneous catalytic gas-phase reactions is that the presence of a boundary between bubble gas and suspension gas leads to the existence of two distinct phases (bubble phase and suspension phase) with drastically different gas–solid contact.

If $\alpha < 1$, some of the gas in the suspension phase undergoes short-circuit flow through the bubble, while only part of the bubble gas recirculates through the suspension. This type of flow is typical for fluidized beds of coarse particles (Geldart group D).

Under the real operating conditions of a fluidized-bed reactor, a number of interacting bubbles occur in the interior of the fluidized bed. As a rule, the interaction leads to coalescence. As detailed studies have shown, this process is quite different from that between gas bubbles in liquids because of the absence of surface-tension effects in the fluidized bed [48, 49].

For predicting mean bubble sizes in freely bubbling fluidized beds, a differential equation for bubble growth should be used in the case of Geldart group A and B solids [50]:

$$\frac{\mathrm{d}}{\mathrm{d}h}\, d_v = \left(\frac{2\varepsilon_b}{9\pi}\right)^{\frac{1}{3}} - \frac{dv}{3\lambda\, u_b} \tag{15}$$

with the following boundary condition at $h = h_o$:

$$\frac{d_{v0}}{\mathrm{m}} = \begin{cases} 0.008\varepsilon_b^{1/3} & \text{porous plate} \\ 1.3\left(\frac{\dot{V}_o^2}{g}\right)^{0.2} & \text{industrial gas distributor} \end{cases} \tag{16}$$

where h_o is the height above the grid where the bubbles form (for a porous plate, $h_o \approx 0$; for a perforated plate, $h_o = L$; for a nozzle plate, h_o is the height of the outlet opening above the plate; and for a bubble-cap plate, h_o is the height of the lower edge of the cap above the plate). $\dot{V}_0$ is the volume flow rate of gas through the individual grid opening.

The local volume fraction of bubble gas ε_b is given by

$$\varepsilon_b = \dot{V}_b/u_b \tag{17}$$

and the visible bubble flow $\dot{V}_b$ is

$$\dot{V}_b \approx 0.8\ (u - u_{mf}) \tag{18}$$

The upward velocity u_b of bubbles depends not only on the bubble size but also on the diameter d_t of the fluidized bed:

where

$$u_b = \dot{V}_b + 0.71 \cdot \vartheta_b \cdot \sqrt{g d_v} \tag{19}$$

$$\vartheta_b = \begin{cases} 3.2\, d_t^{0.33} & 0.05 \le d_t \le 1\ \mathrm{m},\ \text{Geldart group A} \\ 3.2\, d_t^{0.5} & 0.1 \le d_t \le 1\ \mathrm{m},\ \text{Geldart group B} \end{cases} \tag{20}$$

Outside these limits, ϑ_b is taken as constant.

The differential equation (Eq. 15) describes not only bubble growth by coalescence but also the splitting of bubbles (second term on the right-hand side [51]). The crucial parameter here is the mean bubble lifetime λ:

$$\lambda \approx 280 \cdot \frac{u_{mf}}{g} \tag{21}$$

In practice, bubble growth is limited not only by the splitting mechanism based on the particle-size distribution of the bed solids, but also by internals (screens, tube bundles, and the like) that cause bubbles to break up. Computational techniques for estimating this process are given in [52, 53].

Hilligardt and Werther have derived a corresponding bubble-growth model for coarse-particle fluidized beds (Geldart group D) [50].

An example of a measured and calculated bubble-growth curve is presented in Figure 8.

Figure 8. Bubble growth in a fluidized bed of fine particles (Geldart group A; data points from [54], calculation from [50])

2.8. Elutriation

When bubbles burst at the surface of the fluidized bed, solid material carried along in their wake is ejected into the freeboard space above the bed. The solids are classified in the freeboard; particles whose settling velocity u_t is greater than the gas velocity fall back into the bed, whereas particles with $u_t < u$ are elutriated by the gas stream. As a result, both the volume concentration of solids c_v and the mass flow rate of entrained solids in the freeboard show a characteristic exponential decay (Fig. 9). With increasing height above the bed surface, the "transport disengaging height" (*TDH*) is finally reached. Here the increased local gas velocities due to bubble eruptions have decayed, and the gas stream contains only particles with $u_t < u$. When the *TDH* can be reached in a fluidized-bed reactor, this is associated with minimum entrained mass flow rates and solids concentrations, and hence with minimum loading on downstream dust collection equipment. Design of the dust collection system requires knowledge of the entrained mass flow rate G_s and the particle-size distribution of the entrained solids. For the design of the fluidized-bed reactor, the distribution c_v (h) of the solids volume concentration and, for gas–solid reactions, the local particle-size distribution as a function of height in the freeboard must be known.

For solids of Geldart group A, the *TDH* can be estimated with the diagram shown in Figure 10 [55]. The following relation is given for the *TDH* of Geldart group B solids as a function of the size d_v of bubbles bursting at the bed surface [56]:

$$TDH = 18.2 \cdot d_v \tag{22}$$

Equation (25) was, however, derived for a bench-scale unit and may not scale to plant-size equipment.

Figure 9. Schematic drawing of fluidized bed and freeboard

Figure 10. Estimation of transport disengaging height (*TDH*), according to [55]
u_{mb} = Fluidization velocity at which bubble development begins

The mass flow rate G_s of entrained solids per unit area leaving the fluidized-bed reactor is the sum of contributions from the entrainable particle size fractions ($u_t < u$):

$$G_s = \sum_i x_i \cdot \varkappa_i^* \tag{23}$$

Here x_i is the mass fraction of particle-size fraction i in the bed material and $\varkappa^*_i$ is the elutriation rate constant for this fraction. The literature contains a number of empirical correlations for estimating $\varkappa^*_i$ (e.g., [2 – 4]). More physical-based are the elutriation models of WEN and CHEN [57] and of KUNII and LEVENSPIEL [2, 58], which enable not only calculation of the exiting mass flow rate but also estimation of the concentration versus height c_v (h) in the freeboard. The model by SMOLDERS and BAEYENS additionally takes the effect of variable freeboard geometry into account [59].

A literature survey on the factors affecting elutriation and the available modeling tools is given in [60].

2.9. Circulating Fluidized Beds

2.9.1. Hydrodynamic Principles

In REH's state diagram of the fluidized bed [36], the circulating fluidized bed (CFB) is located above the single-particle suspension curve for $Re < 10^2$ and porosities ε greater than about 0.8 (dashed line in Fig. 5). The shortcoming of this diagram is that it does not show an important parameter in the operation of a circulating fluidized bed: the circulating solids mass flow rate per unit area G_s. The diagram of Figure 11 [61] attempts to remedy this by plotting the mean slip velocity u_{sl} between gas and solids

$$u_{sl} = \frac{u}{\varepsilon} - \frac{(G_s/\varrho_s)}{1-\varepsilon} \tag{24}$$

versus the mean solids concentration $c_v = 1 - \varepsilon$, with G_s as the parameter. The limiting conditions are high solids concentration (bed at minimum fluidization) and $c_v \to 0$ with $u_{sl} = u_t$ (isolated single particle). In the circulating fluidized-bed region, slip velocity increases with increasing G_s and can become much higher than the single-particle settling velocity (the physical justification for this statement comes from the formation of strands or clusters of particles). In the entrained-flow region the slip velocities again decrease with decreasing solids concentration.

Figure 11. Fluidized-bed state diagram, according to [61]

The fluidized-bed state diagrams discussed thus far, as well as others (e.g., [62, 63]), are suitable mainly for the qualitative interpretation of flow phenomena. A diagram proposed by WIRTH (e.g., [11, 64, 65]) also provides quantitative assistance in the design of circulating fluidized beds. The schematic in Figure 12 applies to a given gas–solid system described by a constant value of the Archimedes number Ar. The ordinate is the dimensionless pressure drop of the fluidized bed

$$\psi = \frac{\Delta p}{(\varrho_s - \varrho_f)\ (1-\varepsilon_{mf})\ g\,\Delta h} \tag{25}$$

the abscissa is the particle Froude number

$$Fr_p = \frac{u}{\sqrt{\frac{(\varrho_s - \varrho_f)}{\varrho_f} g d_p}} \tag{26}$$

The dimensionless pressure drop ψ is the ratio of the pressure drop Δp along the flow path Δh to the maximum possible value for ascending flow (the value that would be attained if the pipe cross section were filled with solids corresponding to the concentration at the minimum fluidization point). The parameter of the family of curves is a volume flow rate ratio

$$\frac{\mu\ \varrho_f}{\varrho_s\ (1-\varepsilon_{mf})} \tag{27}$$

where μ is the ratio of solid-to-gas mass flow rates. The limiting curve bounds the region of stable, vertically upward gas–solid flow on the low gas velocity side.

Figure 13 shows how the state diagram of Figure 12 is constructed for a circulating fluidized bed with siphon recycle. If solids holdup in the recycle line and siphon is ignored, this case represents operation with a constant bed mass independent of velocity. At high gas velocities and if acceleration effects are neglected,

the bed material is distributed uniformly over the total height H_{cfb} of the fluidized bed (Fig. 13 C). The circulating fluidized bed then exhibits a single steady-state section with a constant pressure gradient ($\Delta p/\Delta h$). This pressure gradient can be calculated from the bed mass as

$$\psi_{\mathrm{hom}} = \frac{(\varrho_{\mathrm{s}}-\varrho_{\mathrm{f}})\,\mathrm{g}H_{\mathrm{mf}}\,(1-\varepsilon_{\mathrm{mf}})}{(\varrho_{\mathrm{s}}-\varrho_{\mathrm{f}})\,\mathrm{g}H_{\mathrm{cfb}}\,(1-\varepsilon_{\mathrm{mf}})} = \frac{H_{\mathrm{mf}}}{H_{\mathrm{cfb}}} \tag{28}$$

where H_{mf} is the bed height at minimum fluidization.

Figure 12. State diagram for the circulating fluidized bed with siphon, according to WIRTH [64]
Ar = const., parameter of family of curves is the volume flow rate ratio $\mu\ \varrho_{\mathrm{f}}/(\varrho_{\mathrm{s}}\ (1-\varepsilon_{\mathrm{mf}}))$; Fr_{p}= particle Froude number for superficial minimum fluidization velocity ($\mathrm{pu}_{\mathrm{mf}}$), single-particle terminal velocity (pt), and transport velocity (pT), respectively.

The states identified by ψ_{hom} to the right of the bounding curve in Figure 12 are accessible by increasing the gas velocity (corresponding to increasing Fr_{p}). With increasing Fr_{p} the volume flow ratio increases; that is, relatively more solids are elutriated (and thus circulated).

If Fr_{p} is allowed to drop below the limit $Fr_{\mathrm{p_{max}}}$ (Fig. 13 B, Fig. 12) two steady-state sections appear in the riser tube: the one in the lower part is marked by a high pressure gradient, that in the upper part by a lower gradient. Figure 13 illustrates the physical significance of these two pressure gradients. In practice, the transition between the two linear regions takes place gradually. The height of the transition zone corresponds to the transport disengaging height (TDH).

The picture changes further if the gas velocity declines to values lower than the settling velocity u_{t} of a single isolated particle. In this case (for $Fr_{\mathrm{p}} < Fr_{\mathrm{pt}}$, Fig. 13 A, Fig. 12), no more solids can be elutriated, and the pressure gradient in the upper linear region vanishes. All the solid material is now in the form of a bubbling or turbulent fluidized bed.

The *solids concentrations* averaged over the tube cross section $(1-\varepsilon)$ can be calculated from the dimensionless pressure drop:

$$1-\varepsilon = (1-\varepsilon_{\mathrm{mf}})\cdot\psi \tag{29}$$

Besides the pressure and solids concentration profile, the *circulating mass flow rate of solids* $G_{\mathrm{s}}\cdot A_{\mathrm{t}}$ is important for the design of the circulating fluidized bed. In particular, the design of the solids collection and recycle system depends very much on this quantity. The mass flow rate of solids depends on the flow regime. At gas velocities such that two steady-state sections are

Figure 13. Pressure profile in the circulating fluidized bed with siphon, according to WIRTH [64]
A) $Fr_{\mathrm{pu_{mf}}}<Fr_{\mathrm{p}}<Fr_{\mathrm{pt}}$; B) $Fr_{\mathrm{pt}}<Fr_{\mathrm{p_{max}}}$; C) $Fr_{\mathrm{p}}>Fr_{\mathrm{p_{max}}}$

present in the bed vessel (i.e., $Fr_{\mathrm{p}u_{\mathrm{mf}}} < Fr_{\mathrm{p}} < Fr_{\mathrm{pT}}$), the mass flow rate of entrained solids depends on the physics of the gas–solid flow. Figure 14 plots the dimensionless solids mass flow rate versus Fr_{p}, with the Archimedes number as parameter. For a given Ar, the flow rate tends to zero as $Fr_{\mathrm{p}} \rightarrow Fr_{\mathrm{pt}}$ and reaches a maximum at $Fr_{\mathrm{p}} = Fr_{\mathrm{pT}}$. The slope of the elutriation curve becomes greater with increasing Ar; that is, the coarser the particles, the greater is the relative change in the circulating mass flow rate of solids with a change in gas velocity.

Figure 14. Elutriation diagram when the circulating fluidized bed contains two steady-state sections, according to WIRTH [64]

At high gas velocities in the circulating fluidized bed (i.e., when a single steady-state section exists), the entrained mass flow rate depends on the particle Froude number and the solids holdup. More detailed information about the application of Wirth's theory in practice may be found in [11].

Whereas WIRTH's analysis of the circulating fluidized bed starts from the pneumatic transport condition, the models of RHODES and GELDART [66], as well as KUNII and LEVENSPIEL [2, 58], are based on the bubbling fluidized bed and describe the circulating fluidized bed as a limiting case of a bubbling bed with a very high rate of solids entrainment.

2.9.2. Local Flow Structure in Circulating Fluidized Beds

The Wirth state diagram, as a first step toward the local characterization of flow regimes in a circulating fluidized bed, describes the vertical profile of the solids concentration. In the lower section of a circulating fluidized bed a dense region exits near the gas distributor. It has been observed that in this bottom zone bubble-like voids coexist with a surrounding dense suspension. The solids volume concentration is higher at the wall ($c_{\mathrm{v}} \approx 0.4$) then in the center ($c_{\mathrm{v}} \approx 0.15$) of the bottom zone [67]. The splash zone which links the bottom zone to the upper dilute zone is characterized by violent gas–solid mixing. Many recent experimental studies with various measurement techniques (e.g., X-ray tomography [68], capacitance tomography [69] and fiber-optical probes [70]) have shown that the upper section of the circulating fluidized bed exhibits characteristic horizontal profiles, with the concentration $c_{v,wall}$ near the vessel wall always significantly higher than the value $\bar{c}_v$ averaged over the vessel cross section; for example, $c_{v,\ \mathrm{wall}} = 2.3 \cdot \bar{c}_v$ [71].

Local measurements of the solids concentration and solids velocity show that upward-flowing regions of low solids concentration and downward-flowing aggregates of high solids concentration alternate in time at every point inside the fluidized bed, with downward-moving aggregates (strands, clusters) predominating near the wall and upward-moving regions of low suspension concentration predominating in the central zone. However, no significant downward flow of solids near the wall was observed in high-density circulating fluidized beds, e.g., [72]. The picture of the local flow structure in a circulating fluidized bed, as derived from these observations, is shown schematically in Figure 15.

A modeling approach which is based on the local flow structure of the CFB is the energy-minimization multiscale (EMMS) model [73]. It considers the tendency of a fluid in a gas–solid two-phase flow to pass through the particulate layer with least resistance and the tendency of the solids to maintain least gravitational po-

tential. Least resistance means that the volume-specific energy consumption for suspending and transporting solids is minimized, and minimization of the gravitational potential is equivalent to the requirement that the local mean voidage ε attains a minimum. The model has been applied as a description of fluid-mechanical phenomena in CFB risers of different sizes [74, 75] but also for the prediction of flow patterns of gas and solids in industrial-scale units, such as a CFB boiler [76] and a petrochemical processing unit [77]. Another promising line of development is the introduction of the EMMS concept into computational fluid dynamical calculations of multiphase flows; first results obtained with a drag model based on the EMMS model are encouraging [78].

Figure 15. Schematic diagram of flow structure in a circulating fluidized bed

2.9.3. Design of Solids Recycle System

Solids carried over with the fluidized gas are generally collected in cyclones. In the case of *bubbling beds*, the solids can easily be returned to the bed through the standpipe of the cyclone, which dips directly into the bed.

Due to the large amounts of circulating solids, *circulating fluidized beds* require very large cyclones arranged beside and outside the bed, with special "valves" needed to connect the standpipe to the bed vessel. Figure 16 shows two design options, the siphon and the L-valve. With the siphon, the solids are fluidized (i.e., enabled to flow back into the reactor). In the L-valve design, the mass flow rate of the solids can be regulated by varying the gas supplied to the standpipe.

Figure 16. Design options for solids recycle
A) Siphon; B) L-valve

Because the solids path does not contain any sort of mechanical closure, the characteristic pressure distribution plotted in Figure 17 is obtained. The distribution of solids between the fluidized bed and the recycle line is directly related to this pressure distribution. Operating properties differ from one recycle design to another [79].

2.10. Cocurrent Downflow Circulating Fluidized Beds (Downers)

A certain drawback of circulating and bubbling fluidized beds when applied for gas-phase reactions is the backmixing which inevitably occurs in the gas phase. In bubbling fluidized beds it is the bubble-induced solids circulation, and in circulating fluidized beds the downflow of solids in the wall zone, which entrains gas in the upstream direction and thus lowers the yield of a catalytic reaction or gives rise to undesired consecutive or side reactions. These disadvantages caused by the hydrodynamic effects of both gas and solids flowing against gravity could be overcome in the so-called downer reactor, in which the flow directions of both gas and solids are downward, i.e., in the same direction as gravity [80]. Another incentive is the possibility of realizing short contact times between gas and solids of around or even below one second.

Downer systems have been intensely studied [80]. Hydrodynamics [81, 82], gas mixing

Figure 17. Pressure distribution in solids recycle system of a circulating fluidized bed
a) Fluidized bed; b) Return leg

[83], and solids mixing [84, 85] have been investigated both experimentally and by numerical simulation [86]. It has been found that the hydrodynamics of the downer are also characterized by a wall zone of increased solids concentration. However, axial and radial gas-solids flow structures are much more uniform than in conventional fluidized beds. Another result is that the length of the flow development zone is much shorter for the downer than for the riser, which means that reactions with very short contact times can be carried out under near-plug-flow conditions. However, the solids feeding process and the geometry of the entrance region are critical points that deserve special attention [87].

The patent and open literature suggest various applications for downer reactors, e.g., residual oil cracking [88], coal pyrolysis [89], and biomass pyrolysis [90]. The catalytic pyrolysis of heavy feeds for the production of light olefins has been investigated on the laboratory scale with promising results [88]. However, no large-scale industrial process has emerged yet.

2.11. Attrition of Solids

The attrition of solid particles is an unavoidable consequence of the intensive solids motion in the fluidized bed. The attrition problem is especially critical in processes where the bed material needs to remain unaltered for the longest possible time, as in fluidized-bed reactors for heterogeneous catalytic gas-phase reactions. Catalyst attrition is important in the economics of such processes and may even become the critical factor.

Figure 18. Attrition modes and their effects on the particle size distribution (q_3 = mass density distribution of particle sizes d_p)

Catalyst attrition in fluidized-bed reactors occurs normally as surface abrasion (Fig. 18) which means that surface asperities are abraded and edges of the catalyst particles are rounded off. Fragmentation may also play a role, especially for some fresh catalyst particles which on

entering the reactor may simply be crushed into pieces. If in an industrial process extraordinarily high catalyst losses are observed it is advisable to examine catalyst samples under the scanning electron microscope. If the sample contains many fragments this could be an indication of a wrong design (e.g., too high a velocity at the cyclone inlet or at the distributor).

When designing catalytic fluidized-bed processes, the attrition performance of candidate catalysts should be tested under standardized conditions in the process development stage. This test can be performed in a small laboratory apparatus; it consists essentially of an extended fluidization test in which the mass of solids carried out of the bed is recorded as a function of time. Figure 19 presents a typical test result: during the first hours of testing, both the attrited material and the fine fraction of the bed material are elutriated. Only after a relatively long operating period is a quasi-steady state attained. The attrition rate r_a in this steady state can be defined as

$$r_a = \frac{1}{m_b} \cdot \frac{\Delta m_a}{\Delta t} \tag{30}$$

where m_a is the elutriated mass and m_b the bed mass. Usually r_a is expressed as percentage per day; for relatively attrition-resistant, fluidized-bed catalysts, it is of the order of 0.2 % per day [9].

Many standard test apparatuses have been proposed for comparative attrition tests (e.g., [91, 92]), but all such equipment has been suitable only for comparative studies of different catalysts under consideration for the same process. The attrition measured in large-scale equipment can be far different from the values measured in a test apparatus.

A number of sources can be identified for catalyst attrition in industrial fluidized-bed reactors:

1) Jet attrition at gas distribution grid openings and nozzles where gaseous reactants are admitted to the bed
2) Bubble attrition in the bed due to solids motion caused by bubbles
3) Attrition in cyclones
4) Attrition in pneumatic conveying lines, such as those between reactor and regenerator beds

Empirical correlations are available for the attriting action of a gas jet in the fluidized bed [93] and for the size reduction effect of solids motion in the bed [94, 95].

WERTHER and coworkers [96] employ the laboratory apparatus shown schematically in Figure 20 which enables separate study of the attrition due to jets from nozzles of various diameters and that due to bubbles.

Figure 19. Result of an attrition measurement

Figure 20. Experimental apparatus for attrition measurement

Under steady-state conditions the jet-attrition-related mass production of fines per unit time for a gas distributor with a number n_o of orifices from mother particles with diameter $d_{p,i}$ which are present in the catalyst inventory with a mass fraction ΔQ_{3i} is proportional to the particle size d_{pi}, the mass fraction ΔQ_{3i}, the density ρ_o of the gas issuing from the orifice, the square of the orifice diameter d_o, and to the cube of the jet exit velocity u_o [97, 98]:

$$\dot{m}_{\mathrm{att,jet},i}=c_j n_0 d_{pi} \Delta Q_{3i} \rho_0 d_0^2 u_0^3 \tag{31}$$

Attrition due to the bubble induced solids movement is given by [98]

$$\dot{m}_{\mathrm{att,bubble},i}=c_b d_{pi} \Delta Q_{3i} m_b (u-u_{mf})^3 \tag{32}$$

where m_b denotes the bed mass which contains bubbles (i.e., which is located outside the jet-dominated grid region). Equation (32) also denotes the mass production of attrited fines which is resulting from the size fraction d_{pi} in the bed.

The stress on the catalyst particles will be different in contact with a gas jet, in the bulk of the bubbling fluidized bed, and during its passage through a cyclone. Recent investigations of cyclone-induced catalyst attrition [99 – 101] have shown that the mass flow of attrited fines which is produced by attrition inside the cyclone when a solids mass flow $\dot{m}_c \cdot \Delta Q_{3ci}$ of particles of the size fraction d_{pi} enters the cyclone is given by

$$\dot{m}_{\mathrm{att,c},i}=c_c \cdot \dot{m}_c \cdot \Delta Q_{3ci} \cdot d_{pi} \cdot \frac{u_c^2}{\sqrt{\mu_c}} \tag{33}$$

where u_c is the gas velocity at the cyclone inlet, and μ_c the solids loading of the incoming gas flow

$$\mu_c=\frac{\dot{m}_c}{\rho_c \cdot u_c \cdot A_c} \tag{34}$$

where ρ_c is the density of the inflowing gas, and A_c the cross-sectional area of the cyclone inlet.

Equations (31)–(34) describe the catalyst attrition under conditions of steady state, i.e., when the particles are more or less rounded off (Fig. 18). To describe also the initial breakage and attrition of fresh catalyst particles, it is necessary to follow the fate of the particles on their introduction into the reactor, which is possible with population balance models (cf. Section 9.3.2). Klett et al. [102] and Hartge et al. [103] have defined a stress history parameter ϑ

$$\vartheta=\begin{cases} t/t_j^* \text{ for jet} - \text{induced attrition} \\ t/t_b^* \text{ for in} - \text{bed attrition} \\ n_p/n_p^* \text{ for attrition in cyclones} \end{cases} \tag{35}$$

where the definition of the characteristic parameters t_j^*, t_b^*, and n_p^* can be taken from Figure 21, n_p is the number of passages of a given particle through the cyclone, and t_b and t_j are the time periods during which the particle is subjected to bubble and jet stress, respectively. If it is assumed that the effects of the different stress mechanisms on the catalyst particles are additive, a uniform treatment of the overall stress history for all three attrition mechanisms is given by

$$\frac{\dot{m}_{\mathrm{att}}(\vartheta)}{\dot{m}_{\mathrm{att},\infty}}=\begin{cases} 1.1 \cdot \vartheta^b & \vartheta \leq 1.1^{-1/b} \\ 1 & \vartheta > 1.1^{-1/b} \end{cases} \tag{36}$$

The parameter b is characteristic of a given catalyst. Figure 22 shows measurements with FCC catalyst [103] which lead to b = −1.16. Equation (36) allows the description of the stress-history-dependent attrition rate and can be used for the simulation of fluidized bed reactors (see Section 9.3.2).

Figure 21. Dependence of attrition on time (bubble- and jet-induced attrition) and number of passages n_p through a cyclone.

A variety of approaches exist for reducing attrition in industrial fluidized-bed reactors. The jet attrition action can be controlled with special gas distributor designs ([9]; e.g., by the use of bubble caps, Fig. 6) such that gas jets do not issue directly into the bed at high velocity. Attrition due to bubbles can be lowered by limiting bubble growth (avoiding high gas velocities and large bed heights; use of fine catalysts with low

u_{mf}, as implied by Eqs. 18 and 24). Attrition in cyclones can be prevented, in the simplest case, by replacing the cyclones with devices such as filters. Attrition can also be minimized by cutting back the load on the cyclone, for example, by placing the cyclones above the TDH. Relatively high catalyst attrition also occurs in circulating fluidized beds where very large quantities of solids must be collected in the cyclones.

Figure 22. Dimensionless attrition rate of FCC catalyst as a function of stress history.

3. Solids Mixing in Fluidized-Bed Reactors

The intensive solids mixing typical of fluidized-bed reactors has several effects on performance. In *catalytic reactions*, the large-scale vertical solids mixing results in a transport of the gas components, adsorbed to the catalyst, so that the gas phase is backmixed and the conversion and selectivity are impaired. In *noncatalytic gas–solid reactions*, the mean solids residence time and residence-time distribution, as well as the propagation behavior of the solids from individual feed points, play a role. In general, fast and strongly exothermic reactions require fairly vigorous solids mixing to prevent temperature peaks near the reactant inlet.

3.1. Mechanisms of Solids Mixing

The wake of the rising bubbles produces a rather slight upward and lateral drift of the particles (Fig. 23 A) [104]. In addition, solid particles are drawn upward in the wake, portions of the wake are shed at irregular intervals during bubble motion, and new portions of solids are taken into the wake (Fig. 23 B). Solids transport in the wake is essentially the reason that vertical solids mixing is from one to two orders of magnitude better than horizontal mixing.

Figure 23. Solids mixing in bubbling fluidized beds due to particle drift (A) and wake transport (B)
a) Cloud; b) Wake

For reasons of continuity, the upward transport of particles by bubbles is coupled with a downward movement in the suspension phase that surrounds the bubbles. Measurements of the local bubble-gas flow have shown that the rising bubbles are not distributed evenly over the bed cross section. As a typical example, Figure 24 A gives a plot of the radial distribution of the bubble-gas flow at three heights above the grid in a fluidized bed 1 m in diameter. The profile is comparatively flat in the bottom zone but exhibits a steeper slope as the height increases, with an annular zone of preferentially rising bubbles. The resulting circulation of the solids also features an annular region of upward transport in the wakes with predominantly downward motion of the solids in the center and at the periphery of the bed (Fig. 24 B).

The large-scale solids circulation can be reinforced by uneven distribution of the fluidized gas over the distributor cross section [106]. Figure 25 presents examples of industrial fluidized-bed furnaces in which forced circulation of the solids is employed to improve coal burnup.

Figure 24. A) Radial distribution of bubble-gas flow; B) Relationship between bubble distribution and solids circulation [105]
d_t = 1 m, quartz sand, u_{mf} = 0.013 m/s, u = 0.2 m/s, H_{mf} = 0.5 m, $\dot{V}_b$ = visible bubble flow

3.2. Vertical Mixing of Solids

The propagation behavior of the solids in a fluidized bed can be described by a number of models (e.g., [2, 109]). Most commonly used is the *dispersion model*, in which solids transport is described by a diffusion law. The numerical value of the dispersion coefficient D_{sv} for solids mixing in the vertical direction increases with increasing gas velocity because of the growth in the number and size of bubbles. The following simple empirical correlation is given for fine particles (Geldart groups A and B) [2]:

$$\left(\frac{D_{sv}}{m^2/s}\right) = 0.06+0.1\left(\frac{u}{m/s}\right) \tag{37}$$

For a *plant-scale fluidized bed* (0.9 × 1.26 m^2 in plan, bed height 4 m) equipped with a bundle of horizontal tubes, a very similar relation was derived for a solid of Geldart group B [110]:

$$\left(\frac{D_{sv}}{m^2/s}\right) = 0.056\left(\frac{u-u_{mf}}{m/s}\right) \tag{38}$$

Because solids circulation becomes more marked in *larger-diameter fluidized beds*, the dispersion coefficient increases rapidly with increasing bed diameter d_t (Fig. 26). For this case the following expression is found [2]:

Figure 25. Fluidized-bed furnaces with forced circulation of solids
A) According to [107]; B) According to [108]

$$\left(\frac{D_{\mathrm{sv}}}{\mathrm{m}^2/\mathrm{s}}\right) = 0.030\left(\frac{d_{\mathrm{t}}}{\mathrm{m}}\right)^{0.65} \tag{39}$$

Figure 26. Vertical solids dispersion in fluidized beds of fine particles (Geldart groups A and B) [2]

The above correlations can provide only rough values. Other effects observed in practice include, in particular, a significant effect of particle-size range [111, 112].

3.3. Horizontal Mixing of Solids

In gas–solid reactions, the propagation behavior of the solids in the horizontal direction is important if, for example, the solid material is fed into the bed at isolated feed points. WERTHER and coworkers model the horizontal propagation of coal in a fluidized-bed furnace, describing the carbon conversion in terms of a simple first-order reaction (rate constant k with dimension s^{-1}) [113]. The crucial parameter is the ratio $\mathrm{k}d_{\mathrm{t}}^2/D_{\mathrm{sh}}$ between the rate of the chemical reaction and the rate of dispersive mass transport. For high values of k (fast reaction), large reactor diameters d_{t}, and low values of the dispersion coefficient D_{sh}, the local carbon concentration in the bed exhibits a rather steep horizontal profile, resulting in a significantly nonuniform distribution of gas emissions over the bed cross section.

On the basis of KUNII and LEVENSPIEL's model of bubble-induced solids mixing [114], an expression has been derived for calculating the horizontal dispersion coefficient D_{sh} averaged over the bed height H, given local bubble properties (bubble diameter d_v, bubble-gas holdup ε_{b}) [115]:

$$D_{\mathrm{sh}}=0.67\times10^{-3}+0.023\,\frac{1}{H}\int_0^H \frac{\varepsilon_{\mathrm{b}}}{1-\varepsilon_{\mathrm{b}}}\cdot\sqrt{g\cdot d_v^3}\,\mathrm{d}h \tag{40}$$

This correlation holds for solids of Geldart groups B and D with Archimedes numbers between 8 600 and 58 000.

3.4. Solids Residence-Time Properties

Many applications of fluidization technology involve continuous processing of solids. Important considerations in such cases are not only the mean solids residence time but also the residence-time distribution. Whereas all elements have the same residence time in a plug-flow system, a stirred tank exhibits a broad distribution of residence times. To a good approximation, the residence-time properties of the fluidized bed with respect to the solids are the same as those of a stirred tank. The mean residence time τ is the ratio of the solids mass m_{b} in the reactor to the solids throughput $\dot{m}_{\mathrm{s}}$:

$$\tau = \frac{m_{\mathrm{b}}}{\dot{m}_{\mathrm{s}}} \tag{41}$$

The mass fraction $\mathrm{d}m_{\mathrm{s}}/m_{\mathrm{b}}$ of solids having a residence time between t and $t + \mathrm{d}t$ is

$$\frac{\mathrm{d}m_{\mathrm{s}}}{m_{\mathrm{b}}} = \frac{1}{\tau}\,\mathrm{e}^{-\frac{t}{\tau}}\,\mathrm{d}t \tag{42}$$

Similarly, the fraction f of solids having a residence time less than t in the bed is calculated as

$$f = 1-\mathrm{e}^{-t/\tau} \tag{43}$$

The residence-time distribution can be narrowed by placing a number of fluidized beds in series. Multistage systems of this type are used, for example, in fluidized-bed drying [18].

3.5. Solids Mixing in Circulating Fluidized Beds

The circulating fluidized bed exhibits a complex gas–solid flow pattern as discussed in Section

2.9. Different regions can be discriminated with respect to the prevailing mechanisms of solids motion and mixing. An extensive survey on experimental findings in solids mixing is given in [116]. In the upper diluted zone of the circulating fluidized bed, clusters are formed with mainly upward flow in the core and predominantly downwards motion near the wall. While the wall region can be modeled by a plug-flow approach, the core region exhibits radial gradients. The Péclet number characterizing radial solids mixing in the core region

$$Pe_{\mathrm{r,\,s}} = \frac{u_{\mathrm{c}} \cdot 2R^*}{D_{\mathrm{r,\,s}}}$$

increases from 150 to 300 with increasing solids volume concentrations [117]. A recent investigation of solids mixing in the bottom zone with solid carbon dioxide as a tracer showed that in this zone solids are almost ideally mixed in the vertical direction but lateral mixing is limited with dispersion coefficients of about 0.1 m^2/s which corresponds to Péclet numbers of around 40, [118].

Counteracting to solids mixing, segregation occurs in applications using particles of a broad size distribution and/or different densities. Easily fluidized particles tend to be elutriated while others tend to sink. A dynamic equilibrium between solids mixing and segregation is established, causing a spatial distribution of particles with significantly different solids properties, as was shown in an experimental study with a mixture of iron powder and quartz sand with a broad particle size distribution [119].

4. Gas Mixing in Fluidized-Bed Reactors

The mixing and residence-time distribution of the gas are particularly important for catalytic reactions but are also significant for gas–solid reactions when gaseous reactants are to be converted to the greatest possible extent in fluidized beds (e.g., reduction of fine-grained iron ores to sponge iron with gaseous reductants [18]). Gas mixing is closely linked to the motion and mixing of the solids in the bed.

4.1. Gas Mixing in Bubbling Fluidized Beds

If the flow and mixing of gas in the bubbling fluidized bed are described by a simple one-phase dispersion model, the coefficients D_{gv} and D_{gh} of gas dispersion in the vertical and horizontal directions have similar numerical values and follow trends similar to those of the solids dispersion coefficients. By way of example, Figure 27 shows the effect of fluidized-bed diameter d_{t} on vertical gas dispersion. The increase in dispersion coefficient with vessel diameter might be attributable to the formation of large-scale solids circulation patterns, which becomes more marked in larger equipment. As in the solids case, the coefficients of horizontal gas dispersion are a factor of 10–100 lower than those of vertical gas dispersion.

Figure 27. Vertical gas dispersion in a fluidized bed of solids of Geldart group A (measurements by various workers; [2])

A single-phase dispersion model gives only a rough description of gas mixing in bubbling fluidized beds. A more exact description comes from models that take account of local flow conditions in the bed, especially the presence of bubbles (see Chap. 9).

4.2. Gas Mixing in Circulating Fluidized Beds

Only a few detailed studies of gas mixing in circulating fluidized beds have been published, which are summarized in [120]. The bubbles

in a bubbling fluidized bed influence the gas residence-time distribution and mixing directly through the bypass action of the bubble-gas flow and gas exchange between the bubbles and the surrounding suspension phase, and also indirectly through the solids motion that they induce. In the circulating fluidized bed, on the other hand, the gas-mixing properties are controlled by segregation due to the formation of solid aggregates (jets, clusters) and the rapid downward movement of solids strands predominantly near the wall. Grace and coworkers, for example, show that a single-phase dispersion model cannot describe the tracer gas residence-time distributions that they measured [121]. They propose instead a two-phase model featuring exchange between a wall zone with stagnant gas and a core zone with plug flow.

For the case of *horizontal gas mixing*, Werther and coworkers [122, 123] have shown that, for the bed solids they used (quartz sand, d_p = 0.13 mm, Geldart group B), horizontal gas mixing in the top part of the circulating fluidized bed in the core zone can be described by the model of turbulent single-phase flow [124]. The Péclet number

$$Pe_{r,\,c} = \frac{u_c \cdot 2R^*}{D_{r,\,c}} \tag{44}$$

(defined in terms of u_c, the superficial velocity in the core zone; R^*, the radius of the core zone; and $D_{r,\,c}$, the horizontal dispersion coefficient in the core zone) has a value of 465, which is in fairly good agreement with values measured in single-phase flows [125]. This value is independent of the solids circulation rate G_s. The circulating fluidized bed thus exhibits no especially intensive horizontal gas mixing, at least in the upper section where solids concentrations are relatively low.

5. Heat and Mass Transfer in Fluidized-Bed Reactors

Fluidized-bed reactors exhibit a uniform temperature distribution even in case of highly exothermic or endothermic reactions. Approximations of the heat transfer rates are necessary for the design and control of fluidized-bed reactors in order to determine the appropriate design of internals for cooling or heating and to estimate the changes in the performance with changing operating conditions.

However, up to now there is no general theory on heat and mass transfer in fluidized beds. Numerous correlations for the calculation of heat and mass transfer coefficients are reported in the literature. Since these correlations are mainly based on experimental investigations performed under laboratory conditions, they may be different to the situation in large-scale reactors. Details on models of heat and mass transfer with their respective range of application are given in related surveys, e.g., [14 – 17, 126, 130].

Fluid-to-Particle Heat and Mass Transfer. Since the particle surface area is very large, fluid-to-particle heat and mass transfer is rarely a limiting factor in the design and operation of fluidized bed reactors. The heat-transfer coefficients of fluidized-beds range between characteristic values for flow through a fixed bed and flow around a single particle [127].

Fixed bed ($Re_p > 80$)

$$Nu = \frac{h_{gs} \cdot d_p}{\lambda_g} = 2 + 1.8\, Re_p^{0.5}\, Pr^{0.33}$$

Single particle

$$Nu = \frac{h_{gs} \cdot d_p}{\lambda_g} = 2 + 0.6\, Re_p^{0.5}\, Pr^{0.33}$$

where h_{gs} is the gas–solid heat-transfer coefficient, d_p the particle size, and λ_g the thermal conductivity of gas. The mass transfer coefficient can be determined applying the analogy of heat and mass transfer by replacing in the above formulas the Nusselt number *Nu* by the Sherwood number *Sh* and the Prandtl number *Pr* by the Schmidt number *Sc*. For particle Reynolds numbers below 100 and for fine particles, the transfer coefficients are significantly lower than estimated by the above formulas. If necessary, the effect of adsorption in mass transfer and of radiation in heat transfer needs to be taken into account additionally.

Heat Transfer to Submerged Surfaces. Heat-transfer coefficients between fluidized bed and submerged surfaces are one or two orders of magnitude larger than for gases alone [126]. For single phase flow a stagnant gas layer is established at the wall causing a hindered heat transfer. This layer is disrupted by solids transported

at the wall. The solids adsorb heat and are mixed into the fluidized bed [9].

An example of the time-averaged local heat transfer along the circumference of a tube immersed horizontally in a fluidized bed is given in Figure 28. It exhibits lower values of the heat-transfer coefficient below the tube due to a gas gap caused by bubbles and lower values on top of the tube because of solids being at rest. With intensified mixing this effect becomes less significant.

Figure 28. Local heat-transfer coefficient around a 35 mm diameter tube immersed horizontally in a fluidized bed of 0.37 mm alumina particles operated at a superficial gas velocity of 0.8 m/s and a temperature of 500 °C, adapted from [128]

The dependence of the heat-transfer coefficient on the superficial gas velocity is illustrated in Figure 29. Fluidized beds of fine particles yield a larger heat-transfer coefficient than coarse particles. According to Molerus and Wirth [126], different transfer mechanisms can be identified. In case of fine particles, solids act as agents transporting heat between walls and bed, whereas gas convective transport is the mechanism dominating the heat transfer of coarse particles. The heat-transfer coefficient of particles of intermediate sizes exhibits a maximum due to the superposition of these two transport mechanisms. Heat-transfer rates in circulating fluidized beds are lower than in bubbling fluidized beds due to reduced solids volume concentrations and are dominated by clusters and strands [130].

The heat-transfer coefficient increases with increasing pressure [131] and temperature. The effect of radiation has to be considered for temperatures above 500°C, but opaque particles can form an effective radiation shield [132].

6. Gas-Solid Separation

The fluidizing gas inevitably carries fine catalyst particles by entrainment to the reactor exit. Not only for environmental reasons (i.e., to minimize emissions) is it necessary to separate the solids from the gas. It may also be necessary to stop the main reaction and to avoid unwanted side or consecutive reactions or to protect following process steps or machines from particle-laden streams. In fluidized-bed technology cyclones are mostly used for this purpose. Knowlton [133] has given a survey on the state of the art of cyclone design and application in fluidized-bed reactors.

The cyclone should not be considered as a separate apparatus following the fluidized bed but should be seen as an integral part of the fluidized-bed process. The reason is that, not only in circulating fluidized beds but also in bubbling or turbulent fluidized beds, the catalyst particles which are recovered in the cyclone are recycled to the fluidized bed. The collection efficiency of the cyclone is thus responsible for maintaining the particle size distribution in the bed inventory, which in turn determines the fluidized-bed fluid mechanics and the chemical performance of the bed as a reactor. The interrelation between fluidized bed and cyclone is discussed in Section 9.3.2.

The influence of cyclone performance on the overall process performance is increasingly considered. For example, Pulupula et al. [134] investigated the role of cyclones in the regenerator system of a commercial FCC unit. Arnold et al. [135] were able to trace the deterioration of plant performance in the ALMA maleic process back to problems with cyclone efficiency. A change of the cyclone design improved the particle size distribution of the bed inventory and consequently bed hydrodynamics and chemical conversion. Smit et al. [136] report on cyclone performance in turbulent fluidized-bed Synthol reactors for Fischer–Tropsch synthesis. Carbon deposition on the catalyst particles influences the bed hydrodynamics, which in turn, via the

Figure 29. Heat-transfer coefficients determined with a tube immersed vertically in a fluidized bed of glass beads of different size operated at ambient conditions, adapted from [126, 129]

elutriation mechanism, influence cyclone performance.

7. Injection of Liquid Reactants into Fluidized Beds

The injection of reactants in liquid form into the bed was already an essential part of the first fluidized-bed catalytic process. In the FCC process (Section 8.1) crude oil is injected at the base of the reactor and evaporated in contact with the hot catalyst particles. The direct heat transfer is very efficient and avoids a separate evaporator for the feed. The cooling action of the evaporating reactant is a further advantage in the case of an exothermal reaction. Liquid-feed injection is therefore practiced not only in the FCC process but also, for example, in the syntheses of aniline (→ Fluid Mechanics), caprolactam (→ Fluid Mechanics), and melamine (→ Fluid Mechanics) and in BP Chemicals' Inovene process [137] for the gas-phase production of low-density polyethylene.

Despite its industrial significance knowledge about the mechanisms of liquid mixing and evaporation in the fluidized bed is relatively scarce. Investigations with nonvaporizing horizontal gas–liquid spray jets have shown that with proper design of the injection nozzle it is possible to penetrate over several decimeters into the bed before the jet breaks up [138, 139]. On the other hand, it was found that under vaporizing conditions for atomizer nozzles with spray angles between 20 and 120° the injected liquid wetted the bed particles and subsequently evaporated from their surface while the particles were mixing in the bulk of the bed [140, 141]. This latter mechanism helps to transport the reactant away from the location of the nozzle and thus contributes to equalization of the feed distribution inside the reactor. The special case that a large oil droplet impinges on a smaller hot catalyst particle was recently investigated in a 3D direct numerical simulation to analyze droplet–particle collisions in the Leidenfrost regime [142]. The calculations were carried out for conditions prevailing near the feed nozzle in an FCC riser. Vapor layer pressure induced by evaporation and the droplet surface tension are the driving forces for droplet recoiling and rebounding. The contact time for a FCC particle and an oil droplet turned out to be about 140 μs.

8. Industrial Applications

In this chapter the industrial uses of fluidized-bed reactors are classified as follows:

1) Heterogeneous catalytic gas-phase reactions
2) Polymerization of olefins
3) Homogeneous gas-phase reactions
4) Gas–solid reactions
5) Biotechnology applications

In each of these areas, the most important applications are listed and a few typical examples are analyzed in more detail. For further descriptions of processes, the reader is referred to relevant articles in the A series. Complete descriptions of industrial uses of the fluidized-bed reactor can also be found in [2, 10, 18, 19].

8.1. Heterogeneous Catalytic Gas-Phase Reactions

The fluidized-bed reactor offers the following principal advantages over the fixed-bed reactor for heterogeneous catalytic gas-phase reactions:

1) High temperature homogeneity, even with strongly exothermic reactions.
2) Easy solids handling, permitting continuous withdrawal of spent catalyst and addition of fresh if the catalyst rapidly loses its activity.
3) Ability to operate in the explosion range, provided the reactants are not mixed until they are inlet to the fluidized bed. This is because the high heat capacity of the bed solids, together with intensive solids mixing, prevents the propagation of explosions.

Figure 30. Fluid catalytic cracking process (Kellogg-Orthoflow system; according to [143, 144])
a) Reactor; b) Regenerator

Catalytic Cracking (→ Oil Refining, Chap. 3.2). The ease of solids handling was the basic reason for the success of catalytic cracking of long-chain hydrocarbons in the fluidized bed (Fig. 30). The cracking reaction is endothermic and involves the deposition of carbon on the catalyst surface, which quickly renders the catalyst inactive. Accordingly, the catalyst must be continuously discharged from the reactor and regenerated in an air-fluidized regenerator bed (b), where its carbon loading is lowered from 1–2 to 0.4–0.8 wt %. The combustion in this bed simultaneously furnishes the heat required for the cracking reactor; the catalyst acts as a heat carrier. The temperature in the regenerator is 570–590 °C and in the reactor, 480–540 °C [2]. In a stripper, steam is admitted to remove hydrocarbons adhering to the catalyst before it is forwarded to the regenerator.

With the advent of high-activity zeolite catalysts in the 1960s, the bubbling fluidized bed, operated at gas velocities between 0.31 and 0.76 m/s [2], was replaced by the *riser cracker* (Fig. 31), in which the oil fed in at the bottom of the riser (c) is vaporized in contact with the hot catalyst and the mixture of oil vapors and cracking gas transports the catalyst up through the riser. In the reactor bed (a), solids are collected before passing through the stripper (b) to the regenerator (f). By virtue of the short contact time of the order of a few seconds and the narrow gas residence-time distribution, the high activity of the zeolite catalyst is optimally utilized and a higher gasoline yield is achieved [2, 10].

Figure 31. Riser cracking process (UOP system), [2]
a) Reactor; b) Stripper; c) Riser; d) Slide valve; e) Air grid; f) Regenerator

Synthesis of Acrylonitrile. The crucial factor in the successful use of the fluidized-bed reactor for the synthesis of acrylonitrile by the ammonoxidation of propene (Sohio process) (→ Acrylonitrile) was reliable control of this strongly exothermic reaction:

$$C_3H_6 + NH_3 + 3/2\,O_2 \rightarrow C_3H_3N + 3\,H_2O \quad \Delta H_r = -515\,\mathrm{kJ/mol\ of\ acrylonitrile.}$$

The reaction is carried out at a bed temperature of 400–500 °C and gas contact time of 1–15 s [145] or 5–20 s [2]. Figure 32 is a schematic of the reactor. Air is fed to the bottom of the fluidized-bed vessel. The reactants ammonia and propene are fed in through a separate distributor (b). Catalyst regeneration by carbon burnoff occurs in the space between the air distributor and the feed-gas distributor. The heat of reaction is removed by bundles of vertical tubes (a) inside the bed (horizontal tubes are used in other designs [146]).

Figure 32. Synthesis of acrylonitrile (Sohio process) [2]
a) Cooler with internals; b) Distributor

Fischer–Tropsch Synthesis. The Fischer–Tropsch synthesis of hydrocarbons is used on a large scale for fuel production in the Republic of South Africa [149]. Synthesis gas generated from coal in Lurgi fixed-bed gasifiers enters the Synthol reactor (Fig. 33), where it is reacted over an iron catalyst at ca. 340 °C. The reactor works on the principle of the circulating fluidized bed. The mean porosity in the riser is 85 %, and the gas velocity varies between 3 and 12 m/s [2]. Reaction heat is removed by way of heat-exchanger tube bundles placed inside the riser.

Figure 33. Fischer–Tropsch synthesis in the Synthol reactor [2, 147]
a) Hopper; b) Standpipe; c) Riser; d) Cooler (coil); e) Reactor; f) Gooseneck

However, experience has shown that this reactor is costly, relatively expensive to operate and maintain, and scale-up to the size of the reactors in operation is probably close to the maximum achievable for operation at 350 °C and 2.5 MPa. Therefore, in the 1990s the 16 circulating fluidized-bed reactors operating at Sasol's Secunda site were replaced by eight turbulent fluidized-bed reactors each of 10.7 m diameter, which achieve a higher per-pass syngas conversion [150].

Different process routes have been developed for the synthesis of maleic anhydride. The Mitsubishi process [152, 153] used the naphtha

cracker C_4 fraction. The ALMA process uses *n*-butane as feedstock [154, 155]. A more recent development is the Du Pont process, which is also based on *n*-butane but uses a circulating fluidized bed as reactor (Fig. 34) [156]. It is based on a vanadium phosphorus oxide (VPO) catalyst which oxidizes *n*-butane to maleic anhydride by a redox mechanism on its surface layers [157]. In the riser *n*-butane is selectively oxidized by the oxidized catalyst. In the fluidized-bed regenerator the spent catalyst is reoxidized. Since 1996 a commercial plant has been operating in Asturias, Spain [158].

Figure 34. The Du Pont maleic anhydride process [158].

Other Processes. Other catalytic reactions carried out in fluidized-bed reactors are the oxidation of naphthalene to phthalic anhydride (→ Phthalic Acid and Derivatives) [2, 10, 151]; the ammoxidation of isobutane to methacrylonitrile [2]; the reaction of acetylene with acetic acid to vinyl acetate [2]; the oxychlorination of ethylene to 1,2-dichloroethane (→ Chlorinated Hydrocarbons) [2, 10, 159, 160]; the chlorination of methane [2]; the reaction of phenol with methanol to cresol and 2,6-xylenol [2, 161]; the reaction of methanol to gasoline [162, 163]; the synthesis of phthalonitrile by ammoxidation of *o*-xylene (→ Phthalic Acid and Derivatives) [164]; the synthesis of aniline by gas-phase hydrogenation of nitrobenzene (→ Aniline, Chap. 3.2) [165]; and the low-pressure synthesis of melamine from urea (→ Melamine and Guanamines) [166].

An overview on the various fluidized-bed catalytic processes has been given [167].

8.2. Polymerization of Olefins

The gas-phase polymerization of *ethylene* in the fluidized bed was developed by Union Carbide (Unipol process [168]; see Fig. 35) (→ Polyolefins). The reaction gas (ethylene and its comonomers butene or hexene) fluidizes the bed at 75–115 °C and 20–30 bar. Extremely fine-grained catalyst is metered into the bed. Polymerization occurs on the catalyst surface and yields a granular product with diameter ranging from 0.25 to 1 mm. Ethylene conversion is comparatively low, 2 % per pass; so the reaction gas is recycled. The heat of reaction is removed by cooling the recirculating gas. The catalysts used have such a high activity that more than 10^5 parts by volume of polymer can be produced per unit weight of active substance in the catalyst [2]. Because of the high degree of catalyst dilution in the granular polymer, the catalyst need not be removed from the product. In the process developed by BP Chemicals, prepolymers with a diameter from 0.2 to 0.25 mm rather than catalyst particles are fed into the fluidized bed [169].

Mitsui Petrochemical Industries has developed a process for the gas-phase fluidized-bed polymerization of propene (→ Polyolefins); a plant using this process came on stream in 1984 [170]. The Unipol–Shell process was jointly developed by Union Carbide and Shell and commissioned in 1986.

Burdett et al. [171] have given a broad overview on this still-developing technology, which presents many challenges for the engineer. One of the biggest problems is the stickiness of the particles under the operating conditions of the process, which has often led to particle sintering with subsequent defluidization of the bed. Seville et al. [172] monitored the motion of particles in a scaled polymer reactor and studied the sintering kinetics in order to determine

a safe operating window. Cai and Burdett [173] developed a model of single-particle polymerization in the fluidized bed to simulate particle growth and particle-temperature evolution with the residence time of a catalyst particle in the reactor.

8.3. Homogeneous Gas-Phase Reactions

The decisive advantage of the fluidized bed for homogeneous gas-phase reactions is the ability to carry large quantities of heat into or out of the reactor by using direct heat exchange via the bed solids. An example is the *Exxon fluid coking process* (Fig. 36; [2, 18, 174, 175]), which converts heavy residual oils to petroleum coke and gas-oil. The reactor (d) and heater (e) beds are connected in a single solids loop. The bed material is coke generated in coking at 480–570 °C, which grows to spherical particles 0.1–1 mm in diameter in the reactor. The coke is discharged continuously from the reactor and heated to 500–690 °C by partial combustion in the heater. The hot coke stream then transports the heat needed for the endothermic coking reaction into the reactor. Excess coke is removed as a coarse fraction in a classifier connected to the heater. Fluid coking is used, e.g., for refining bitumen from the Athabasca tar sands in Canada. To make efficient use of the product coke, Exxon combined the fluid coking process with a fluidized-bed gasification reactor [2, 175]. This Flexi-Coking process was first implemented in 1976 in Japan; the daily capacity of one plant is ca. 3400 t of vacuum residue.

Figure 36. Fluid coking process [2, 18]
a) Slurry recycle; b) Stripper; c) Scrubber; d) Reactor; e) Heater; f) Quench elutriator

The bed solids also find use as heat-transfer agents in the *thermal cracking of naphtha*, a process carried out in the Lurgi sand cracker [2, 18, 176]. The solids circulating between the reactor and the heater consist of coarse sand particles (ca. 1 mm in diameter). When the coke deposit produced in cracking is burned off the particle surface with air, the solids are heated to 800–850 °C and can thus deliver the heat required for endothermic cracking. The temperature in the reactor is ca. 700–750 °C.

Other thermal cracking processes include the BASF Wirbelfliess process [2, 18, 177], and the Kunii–Kunugi process [2].

8.4. Gas–Solid Reactions

Coal Combustion. The high heat capacity of the fluidized bed permits stable combustion at low temperature (ca. 850 °C), so that the formation of thermal and prompt nitrogen oxides [178] can be suppressed and total nitrogen oxide emissions can be reduced. If limestone is added to the bed, the calcination reaction

Figure 37. Power plant with circulating fluidized-bed furnace (Lurgi process) [180]

$$CaCO_3 \rightarrow CaO + CO_2$$

yields CaO, which can bind in situ the SO_2 produced in combustion:

$$SO_2 + CaO + 1/2\,O_2 \rightarrow CaSO_4$$

During the 1980s the fluidized bed was established in power-plant engineering. The unit size rapidly increased from 5 MW_e in 1970 to about 350 MW_e during this time [179]. Meanwhile (ca. 2006) some 500 power plants are in operation worldwide. By far the majority of these plants operate with circulating fluidized beds. As an example, Figure 37 shows a Lurgi design.

The staged admission of the combustion air minimizes NO production from nitrogen in the fuel in the lower part of the combustion chamber. The admission of secondary air completes the combustion in the upper part of the chamber by oxidizing most of the CO. Some of the circulating solids are led through the external fluidized-bed cooler, which enhances the flexibility of control and permits load variation over a wide range.

More recent developments aim at even larger capacities with a further enlargement of the combustion chamber and making use of supercritical steam conditions and once-through boiler design. One problem associated with the size enlargement is the distribution of both the coal and the secondary air from the sidewalls over the cross section of the combustion chamber. Since the lateral mixing of gas and solids in a circulating fluidized bed is quite slow, sufficient numbers of feed ports for the coal and air injection nozzles have to be arranged on the sidewalls. The "pants-leg" design shown in Figure 38 is one possibility to provide sufficient lateral mixing at the bottom of the combustion chamber. A first 450 MW_e unit is being built in Lagisza/Poland [181] and 600 MW_e CFB combustors are in the design phase [182].

If a fluidized-bed furnace running under a pressure of 12–16 bar is linked to a gas turbine, the efficiency of the power plant can be markedly enhanced [183]. At the same time, however, this concept imposes severe requirements on gas cleaning [184]. Pressurized fluidized-bed combustion has been tested in several large experimental plants (e.g., [186]). In the meantime several plants of the 80 MW range are in commercial operation. Recently, a pressurized fluidized-bed combustor with an electrical power of 360 MW was erected by ABB Carbon [185] (Fig. 39); these units employ bubbling fluidized beds [187, 188]. Pressurized fluidized-bed boilers employing circulating fluidized beds are still under development (e.g., [189]).

For further details on fluidized-bed combustion systems see the proceedings of the Fluidized

Bed Combustion Conferences [25] and a monograph [190].

Waste Incineration. The incineration of *municipal sewage sludge* in fluidized-bed furnaces is now practiced in many facilities [191]. The total amount of sludge thermally treated in Germany in 1996 was 513 000 t (dry basis) [192]. Figure 40 is a diagram of an incinerator. Moist, centrifuged sludge is fed from above to

the fluidized bed by means of piston pumps. The fluidizing air is preheated in an oil-fired muffle before reaching the furnace. Fuel oil, used as a supplemental fuel, is metered directly into the bed. Developments in sludge incineration have achieved energy autarky by recovering waste heat and utilizing it to predry the sludge so that self-sustaining combustion is possible [194 – 196]. Later, the more stringent emission limits set forth in the 17th Bundesimmissionschutzverordnung (BImSchV, regulation in the Federal Republic of Germany concerning the limitation of immissions) may necessitate staged combustion (as in power generation), particularly to control NO_x emissions [197, 198].

Figure 40. Fluidized-bed furnace for municipal sludge incineration (Uhde system) [193]

For the *incineration of municipal waste*, a furnace with a "rotating" fluidized bed has been developed. The inclined distribution grid in this design generates two rollerlike flows of circulating bed solids, leading to rapid and efficient mixing of the waste in the bed [199].

Coal Gasification. A number of fluidized-bed processes have been developed for gasifying coal (→ Gas Production; e.g., [2]). Interest in these processes for cogeneration power plants has recently become more intense. In the cogeneration system shown in Figure 41, high-pressure gasification is combined with combustion in a circulating fluidized bed; efficiencies of more than 40 % are expected, depending on the available gas turbine technology [180]. The Rheinische Braunkohlenwerke company has developed a high-temperature Winkler (HTW) process based on Winkler gasification (Fig. 42) [200]. The pressure (ca. 10 bar) and temperature (ca. 1100 °C) are higher than in the Winkler process; coal is gasified with oxygen and steam. Recycling of solids from the cyclone to the fluidized bed results in a much higher carbon conversion than in the Winkler process.

Gasification of Solid Waste. In comparison with incineration, the gasification of solid waste offers the advantage of a smaller volume of off-gas, so the cleaning system can be made smaller. In the Japanese Pyrox process, heat required by the gasification reactor is supplied by sand heated in a fluidized-bed furnace, so that a high-Btu-gas can be generated [2].

A cement kiln plant at Ruedersdorf in Germany is operated with a biomass gasification reactor. This circulating fluidized-bed reactor designed by Lurgi supplies fuel gas for the calciners [201].

Calcination. The calcination of aluminum hydroxide in the Vereinigte Aluminiumwerke (VAW)/Lurgi circulating fluidized-bed process features an overall thermal efficiency of more than 70 %, which is achieved through downstream heat recovery from the calcined alumina and the off-gas [18, 202 – 204]. The circulating fluidized bed proper (c) is coupled to two venturi fluidized beds (a), in which the moist hydroxide is first dried and heated by direct contact with the off-gas before it is forwarded to the calcination furnace (see Fig. 43). The five-stage fluidized-bed cooler (d) downstream of the furnace serves to preheat the combustion air. A furnace 3.8 m in diameter and 20 m tall, with a fluidization velocity of 3 m/s and mean particle diameter of 0.04–0.05 mm, produces more than 500 t/d of Al_2O_3 [18].

Other applications include the calcination of limestone (in multistage fluidized-bed furnaces), lime muds, and crude phosphates [2, 18].

Roasting Processes. Fluidized-bed roasting follows the general reaction equation

Figure 41. Concept for cogeneration power plant based on high-pressure gasification in circulating fluidized bed [185]

Metal sulfide + Atmospheric oxygen

→ Metal oxide + Sulfur dioxide

This is one of the earliest industrial uses of fluidization. Many such processes are used in the roasting of pyrite, zinc blende, and other sulfide ores. Bubbling fluidized beds with gas velocities between 0.5 and 2.3 m/s [2] are employed; heat generated by the exothermic roasting reaction is removed by tube banks immersed in the bed, via a solid heat-transfer agent, or by simple water injection. Roasting furnaces are available in very large sizes (bed diameters up to 11 m) with capacities of several hundred tonnes of ore per day [2, 18].

Iron Ore Direct Reduction. (→ Iron). For the direct reduction of iron ore, Lurgi has developed two processes [205]. Hydrogen is applied as reductant in the Circored process, coal gas is used in the Circofer process. A plant for the Circored process has been built in Trinidad with a capacity of 500 000 t iron briquette per year [206]. Applying two stages, a circulating fluidized-bed reactor reduces the preheated iron ore (800 °C) at 630–650 °C to a degree of metallization of 65–85 % and a bubbling fluidized-bed reactor proceeds at temperatures up to 680 °C to achieve a degree of metallization of 93–95 % (see Fig. 44). The metallized product is then transported to the hot briquetting unit. At a pressure of 4 bar, the process gas is recycled to a gas cleaning unit and made up with hydrogen.

Other Processes. Fluidized-bed processes for the production of high-purity silicon and activated carbon and the chlorination and fluorination of metal oxides are described in [2]. A detailed description of TiO_2 synthesis in a fluidized-bed reactor and a survey of the use of fluidized-bed processes in the production of nuclear fuels are given in [10].

8.5. Applications in Biotechnology

A comprehensive survey of the use of fluidized-bed reactors in biotechnology is given in [10, 207].

Liquid–solid and liquid–gas–solid systems are used in aerobic and anaerobic wastewater treatment (nitrification and denitrification); the microorganisms are grown as a biofilm on particulate supports to prevent their entrainment from the reactor with the fluidizing medium. The advantages of the fluidized-bed reactor over the fixed-bed reactor include higher capacity per unit volume and less susceptibility to plugging [208]. A study showing the potential of liquid–solid circulating fluidized beds in biotechnological processes such as fermentation has been published recently [209].

Full-scale fluidized-bed *biogas production reactors* have come on stream since 1984 [210, 211]. The process consists of two stages, acidification and methanation. Sand particles 0.1–0.3 mm in diameter serve as support for the microorganisms; at fluidization velocities of 8–20 m/h, the biofilm grows to a thickness of 0.06–0.2 mm on these particles. The reactors are large devices with diameters of 4.6 m and bed heights of 21 m.

Figure 45. Solid-state fermentation of *Aspergillus sojae* in the fluidized bed (adapted from [216])
a) Separator; b) Electrode; c) Agitator; d) Distributor; e) Ejector

Gas–Solid Systems. Gas–solid fluidized-bed fermenters have been investigated on a pilot scale for the growth of *Saccharomyces cerevisiae* [212], the production of ethanol with *S. cerevisiae* [213, 214], and the enrichment of glutathione in yeast by *S. cerevisiae* [214, 215]. In these applications, the substrate is metered into the bed in liquid form. A process used in Japan for the culture of *Aspergillus sojae* on wheat groats employs a solid substrate [216, 217]. The latter process is in service on a plant scale (bed mass 500 kg, bed diameter 1.5 m). The reactor (Fig. 45) contains an agitator (c) just above the distributor (d), as well as a rotating separator (a) in the top of the vessel. Water is sprayed onto

the bed from above to maintain the proper moisture level; electrodes (b) dipping into the bed measure this parameter. The moisture content of the solids is generally a critical parameter for the fluidized-bed fermenter; the bioreactions extinguish if it becomes too low, whereas the particles agglomerate and fluidization is disrupted if it becomes too high. Sterilized air is used for fluidization. Seed spores of the microorganisms are fed into the bed via the ejector (e). This system achieves a considerable gain in cell yield and an enrichment of certain enzymes by a factor of 5–15 over conventional fixed-bed cultures. The generated biomass forms the basis for soy sauce production.

9. Modeling of Fluidized-Bed Reactors

9.1. Modeling of Liquid–Solid Fluidized-Bed Reactors

An expansion formula of the Richardson–Zaki type, Equation (7), describes the hydrodynamics of liquid–solid fluidized beds fairly well [218]. The difficulty in modeling this kind of reactor for bioreactions thus lies not so much in determining the flow and mixing conditions in the fluid as in describing the diffusion processes in the biofilm and the kinetics of the biological reactions [219]. In view of the small number of experimental studies reported thus far, no final judgment can be made on the suitability of various models [208].

9.2. Modeling of Gas–Solid Fluidized-Bed Reactors

Exhaustive literature surveys can be found in [2, 9, 10, 220]. [221]. Many models exist in the literature, which are classified in the cited references under various schemes. The available information can be summed up as follows: No generally accepted model of the fluidized-bed reactor exists; instead, many models have been proposed on the basis of more-or-less extensive experimental findings for various applications.

Any fluidized-bed reactor model can be broken down into separate components that describe, with varying degrees of accuracy, the hydrodynamics (depending on solid properties, operating conditions, and geometry), gas–solid contact, and reaction kinetics. The essential point is that the reactor geometry effect, which is important for scale-up (Chap. 10), manifests itself in the flow conditions and must therefore be included in the hydrodynamic part of the model.

Before a reactor model found in the literature can be applied to a given problem, the designer must determine whether numerical values are available for all model parameters, that is, whether the model is appropriate for design calculations or is a "learning model" [222] in which the numerical values of important parameters can be determined only after the model is adapted to actual test results.

Reaction kinetics may be determined in a fixed-bed reactor, provided measurements are performed under conditions comparable to those that prevail in the fluidized-bed reactor (e.g., the same solids composition and particle-size distribution, the same activity state in the case of catalysts) [223]. However, the kinetic parameters can also be determined directly by measurements in a bench-scale fluidized-bed apparatus [224].

9.2.1. Bubbling Fluidized-Bed Reactors

By far the majority of fluidized-bed reactor models described in the literature deal with reactions in bubbling fluidized beds [2, 9, 10, 225, 226]. For a specific application, modeling depends on the bubble flow regime. For *slow-bubble systems* (Fig. 7, left), the short-circuit flow of gas through the bubbles must be taken into account [227]. For *fast-bubble systems* (Fig. 7, right), the species have to be balanced separately in the bubble and suspension phases.

If models from the literature are employed, it should be taken into account that those devised in the past, when adequate computing hardware was not available, often sought to obtain analytical expressions for the degree of conversion of a single reaction (usually taken as first-order). The simplifying assumption of a single "effective" bubble size for the entire fluidized bed was therefore made [2], or the mass-transfer area between the bubble and suspension phases was taken as uniformly distributed over the height of the bed (HTU or NTU concept, where HTU

denotes height of transfer unit and NTU denotes number of transfer units [228]. Today, in view of the computing power available at the PC level, the recommended procedure is to start from local mass-transfer relations, write balance equations for the differential volume element of the reactor, and then numerically integrate these equations.

Figure 46 presents a model used by WERTHER for a constant-volume reaction [224, 229]. Here the simplifying assumption is that flow through the suspension phase is at the minimum fluidization velocity u_{mf}. For a heterogeneous catalytic gas-phase reaction, the material balances for species i in the unsteady-state cases are as follows:

Bubble phase

$$\varepsilon_{\mathrm{b}} \frac{\delta C_{\mathrm{b}i}}{\delta t} = -\left[u - u_{\mathrm{mf}}\left(1-\varepsilon_{\mathrm{b}}\right)\right] \cdot \frac{\delta C_{\mathrm{b}i}}{\delta h} - k_{\mathrm{G},i} a \left(C_{\mathrm{b}i} - C_{\mathrm{d}i}\right) \tag{45}$$

Suspension phase

$$\begin{aligned}&\left(1-\varepsilon_{\mathrm{b}}\right)\left[\varepsilon_{\mathrm{mf}} + \left(1-\varepsilon_{\mathrm{mf}}\right)\varepsilon_i\right] \frac{\delta C_{\mathrm{d}i}}{\delta t} = \\ &-u_{\mathrm{mf}}\left(1-\varepsilon_{\mathrm{b}}\right) \cdot \frac{\delta C_{\mathrm{d}i}}{\delta h} + k_{\mathrm{G},i} \cdot a \left(C_{\mathrm{b}i} - C_{\mathrm{d}i}\right) \\ &+ \left(1-\varepsilon_{\mathrm{b}}\right) \cdot \left(1-\varepsilon_{\mathrm{mf}}\right) \varrho_{\mathrm{s}} \sum_{j=1}^{M} \nu_{i,j}\, r_j\end{aligned} \tag{46}$$

In Equations (45) and (46) the following simplifying assumptions have been made:

1) Plug flow through the suspension phase at an interstitial velocity ($u_{\mathrm{mf}}/\varepsilon_{\mathrm{mf}}$)
2) Bubble phase in plug flow, bubbles are solids free
3) Reaction in suspension phase only
4) Constant-volume reaction (see [224] for handling a change in number of moles)
5) Sorption effects neglected (see [229] for handling sorption)

Here ε_i is the porosity of the catalyst particles; a is the local mass-transfer area per unit of fluidized-bed volume, which can be calculated as

$$a = \frac{6\varepsilon_{\mathrm{b}}}{d_v} \tag{47}$$

for spherical bubbles; r_j is the rate of partial reaction j per unit mass of catalyst; and ν_{ij} is the stoichiometric number of species i in reaction j. The relation

$$k_{G,i} = \frac{u_{\mathrm{mf}}}{3} + \sqrt{\frac{4 D_i \varepsilon_{\mathrm{mf}} u_b}{\pi d_v}} \tag{48}$$

proposed by SIT and GRACE [230] has proved useful for describing the mass-transfer coefficient $k_{\mathrm{G}i}$ associated with component i in mass transfer between the bubble and suspension phases; D_i is the molecular diffusion coefficient of species i.

The *freeboard space* above the bubbling fluidized bed must be considered in the reactor model if the entrainment rate is high and the reactions in the freeboard are not quenched, for example, by cooling.

Most fluidized-bed models include concentration profiles only for the vertical direction. This one-dimensional modeling is acceptable when the reactants are admitted uniformly over the bed cross section. If, however, reactants are metered into the bed at individual feed points, three-dimensional modeling may become necessary. Such models have been devised for the combustion of coal in bubbling fluidized beds [232 – 234].

As a rule, the *modeling of solids* behavior in bubbling fluidized-bed reactors is based on that in stirred tanks. Fluidized-bed combustion is one of the few exceptions; here the model must take account of the propagation of coal from the feed point if the furnace emission behavior is to be described correctly [232, 234].

Temperature homogeneity is a virtually fundamental property of the fluidized-bed reactor. Even so, one exception is industrially important: in high-pressure fluidized-bed furnaces, the high energy density can cause local hot spots near the fuel injection points [235]. Reactor models that take care of this have been described, e.g., in [236].

9.2.2. Circulating Fluidized-Bed Reactors

In the early days of circulating fluidized-bed reactor modeling, negligible axial dispersion and laterally uniform flow structure were believed to characterize these systems. Thus, simple plug-flow models were used [237]. This approach was found to oversimplify the behavior of circulating fluidized-bed reactors, because a significant amount of axial dispersion was observed. As a result, the plug-flow model has often been modified by adding a dispersion term to the balance equations. Axial dispersion coefficients have

Figure 46. Two-phase model of the fluidized-bed reactor

been determined by many authors who measured the residence time distribution of tracer gases [238, 239]. Typical values of Péclet numbers they found are on the order of 10.

By means of a model reaction it has been proved that in many cases circulating fluidized-bed reactors cannot be characterized by solely considering mixing phenomena [240]. Instead, the presence of mass-transfer limitations and bypassing was found to have a significant influence. In analogy to low-velocity fluidized beds a detailed description of the local flow structure within the reaction volume must serve as a basis for appropriate reactor modeling.

The highly nonuniform flow structure of circulating fluidized beds described in 2.9.2 has led to reactor models which separately deal with different axial zones. The bottom zone–if it exists under the given operating conditions–can be described by models whose basic approaches were originally developed for modeling of bubbling fluidized beds [241]. Modeling of the upper section of the circulating fluidized bed is in most cases based on a proper description of the heterogeneous core–annulus flow structure [242 – 244]. These state-of-the-art models are one-dimensional and define two phases or zones which are present at every axial location:

1) A dense phase or annulus zone: high solids concentration, gas stagnant or moving downwards
2) A dilute phase or core zone: low solids concentration, gas flowing quickly upward.

Similar to the situation in bubbling fluidized beds, the two phases exchange gas with each other and are modeled by separate equations which are obtained from mass balances for each component in each phase.

Today's models still suffer from the problem that not all fluid-mechanical variables can be predicted on the basis of the operating conditions. Instead, reasonable estimations or measurements in cold-flow models are used to obtain numerical values for many variables.

A common feature of all models for the upper part of circulating fluidized beds is the description of the mass exchange between dense phase and dilute phase. In analogy to low-velocity fluidized beds the product of the local specific mass transfer area a and the mass-transfer coefficient k may be used for this purpose. Many different methods for determination of values for these important variables have been reported, such as tracer-gas backmixing experiments [241], non-steady-state tracer-gas experiments [245], model reactions [244] and theoretical calculations [243].

Similar to the bubbling fluidized-bed reactor, the solids behavior of the circulating fluidized-bed reactor can usually be described as completely mixed. This does not hold for riser reactors with very high gas velocities, such as those used in FCC risers ($u > 10\ ms^{-1}$). Here, better modeling results will be obtained by assuming dispersed plug flow of solids [239].

Like for bubbling fluidized beds, it can be assumed that circulating fluidized beds exhibit a high degree of temperature homogeneity even in the case of highly exothermic reactions. However, in the case of very large circulating fluidized beds for coal combustion, significant hor-

Figure 47. The multiscale approach for CFD modeling of fluidized-bed reactors [254].

izontal and vertical temperature profiles have been observed inside the combustion chambers [246].

Despite the many uncertainties, circulating fluidized bed reactors have been modeled successfully. For example, three-dimensional gas and solids concentration profiles were calculated in circulating fluidized-bed boilers with local injection of reactants [247] and coal feeding via discrete feeding points [248].

9.3. New Developments in Modeling Fluidized-Bed Reactors

9.3.1. Computational Fluid Dynamics

The models described above follow the "classical" chemical engineering approach which replaces the complex particle–fluid interaction in the fluidized bed by idealized configurations (plug flow, stirred tank, either valid overall or in regions) with mixing and mass-transfer coefficients describing the transport of matter. However, more recently, there has been a strong tendency to model the fluid mechanics of fluidized-bed reactors from first principles. The problem of computational fluid dynamics (CFD) modeling in this area is that the particle–particle and particle–fluid interaction must be considered on the particle scale, while the reactor performance must be described on a much larger scale, typically on the order of several meters. This leads to computational difficulties and problems with available computing capacities. At present (ca. 2006) there is no generally accepted CFD model of the fluidized-bed reactor available, but rapid progress can be seen in this area [249 – 253]. A promising approach appears to be multiscale modeling strategy [254].

The idea essentially is that fundamental models which take into account the relevant details of fluid–particle (lattice Boltzmann model) and particle–particle (discrete-particle model) interactions are used to develop closure laws to feed continuum models which can then be used to simulate the flow structures on a larger scale. Figure 47 illustrates this approach, which finally leads to the discrete-bubble model and should be applicable to the large industrial scale of the

Figure 48. Fluidized-bed reactor model system [256].

Figure 49. Reactor behavior as a function of operating time [256].

bubbling fluidized-bed reactor. The multiscale methodology [255] still requires development work but provides a good chance to arrive at more realistic fluidized-bed reactor models in the not too far future.

9.3.2. Modeling of Fluidized-Bed Systems

Another line of development is the modeling of fluidized-bed reactor systems. Whereas previously the isolated fluidized bed was modeled,

the focus now is on the coupling between the fluidized bed and the cyclone for catalyst recovery and recycle [256] or even on the coupling between two fluidized-bed reactors [257], e.g., reactor–regenerator systems as are used in the FCC and maleic anhydride processes.

Figure 50. Influence of the Sauter diameter on the chemical conversion of a simple first-order reaction [256].

As an example, Figure 48 shows a fluidized-bed coupled with a cyclone and its translation into the model system. Attrition leads to a loss of material from the system, which requires the addition of fresh catalyst after some time (Fig. 49). A population balance model which considers the changes in the catalyst particle size intervals allows the change in the catalyst inventory with time to be followed. We see that it takes several weeks for the system to reach a quasisteady state. As a consequence of attrition and incomplete separation in the cyclone, the mean particle diameter in the bed increases with time, and this leads to larger bubbles and a reduced area of mass transfer between bubbles and the surrounding suspension in the bed. As a further consequence the conversion rate of a simple first-order reaction falls off with time. Finally, Figure 50 shows that improvements in the efficiency of the solids-recovery system are able to increase the conversion rate again, which is in agreement with large-scale industrial experience [258, 259].

10. Scale-up

Typical diameters of bench-scale fluidized-bed reactors are roughly 30–60 mm, and of pilot-scale units 450–600 mm, which should allow a reliable scale-up [9]. Full-scale fluidized-bed reactors used in the chemical industry have diameters up to ca. 10 m. Circulating fluidized bed combustors are even bigger with bed cross-sectional areas reaching 200 m^2 [261]. As equipment size increases, characteristic changes take place in the gas–solid flow that can decisively affect reactor performance. Such changes result either directly from the geometry or indirectly from design changes made as the unit is enlarged. In particular, experience has shown that the following factors affect the performance of bubbling fluidized beds during scale-up [262]:

Bed Diameter. According to Equation (22), the mean upward bubble velocity increases as the bed diameter d_t increases. As a result, the bubbles have a shorter residence time in the bed; hence the exchange area between the bubble and suspension phases is smaller, so conversion is reduced [263]. In case of circulating fluidized-bed combustors, measurements have shown that the downwards velocity of solids in the wall zone increases drastically with increasing size of the combustor [260].

Grid Design. In the laboratory, porous plates are the preferred type of gas distributor because of the ease of working with them. Gas distribution becomes worse when these are replaced by industrial distributor designs; thus the exchange area between the bubble and suspension phases is reduced, again with consequently lower conversion [43].

Internals. Whereas the laboratory fluidized bed is generally operated with no internals, plant equipment often must contain bundles of heat-exchanger tubes. Screens, baffles, or similar internals are frequently used to redisperse the bubble gas in industrial reactors. The mass-transfer area is thus increased relative to the fluidized bed without internals; the extra area can be utilized to partially offset the conversion-reducing effects of bed diameter and gas distributor [263].

Catalyst Particle-Size Distribution. Bubble growth is influenced by the proportion of fines in the particle-size distribution of the bed (usually measured as the weight fraction $<$ 0.044 mm) or by the mean grain size d_p (via

u_{mf}, Eq. 18). If the content of fines increases, bubbles collapse sooner and the equilibrium bubble size becomes smaller, with a resultant greater bubble–suspension mass-transfer area. This effect generally is fully developed only in the plant-scale reactor, where bubbles can grow without the hindrance of vessel walls. Thus, in principle, the performance of catalytic fluidized-bed reactors can be controlled by modifying the catalyst particle-size distribution [112, 264]. The recommended content by weight of fines ($<$ 0.044 mm) for "good fluidization" is 30–40 % [265], but maintaining this high a fines content in the system over a long span of time requires a very efficient solids recovery system.

Lateral Mixing of Reactants. On a laboratory scale, reactants experience compulsory uniform distribution over the bed cross section. In plant equipment, on the other hand, reactants often arrive in the reactor via individual feed points. The resulting uneven distribution of reactants can have a marked effect on reactor performance, which has been shown for the effect of coal feeding on the emission properties of fluidized-bed furnaces [248].

Secondary Reactions in the Freeboard. In a bench-scale apparatus, the fluidized gas is rapidly cooled by the vessel wall in the freeboard space after leaving the bed, so secondary reactions in the freeboard are often negligible. Such is not the case in the plant-scale reactor. The action of wall cooling is not significant here, and the entrainment rate is high because of the higher fluidization velocities common in full-scale equipment. Both effects—lack of cooling and high solids concentration in the freeboard—may lead to marked secondary reactions in the freeboard of industrial fluidized-bed reactors. In the case of a system of consecutive reactions where the desired product is formed as an intermediate, the freeboard reactions will generally lower the selectivity. The effect of freeboard reactions has been demonstrated for the example of NO and CO emissions from a fluidized-bed furnace [232].

Catalyst Attrition. Catalyst attrition is minimal in laboratory apparatus, because of the use of porous plates as gas distributors, as well as the low gas velocities and bed depths. Attrition is necessarily greater in industrial reactors. To reduce this risk in scale-up, the attrition tests described in Section 2.11 should be carried out and the results converted to the full-scale conditions with the aid of Equations (34), (35) and (36).

Other Factors. In addition to the factors just listed, many other effects become apparent when a fluidized-bed reactor is scaled up that are difficult to calculate. Examples are the risk of nonuniform gas distribution over very large cross sections in shallow fluidized beds; the formation of deposits in the bed; the fouling of heat-exchange surfaces; and catalyst aging and poisoning. On the whole, accordingly, the scale-up of fluidized-bed reactors is a complex process, commonly requiring a large amount of pilot-scale experimentation. Current knowledge about the fluid mechanics in the fluidized bed, however, enables simulation calculations of many of the scale-up effects, so the amount of testing during process development may be decreased and the risk can be at least limited.
